Prognostic and Diagnostic Value of the Leucocytes and Differential Count in Acute Abdominal Infection.—J. J. Coons and H. O. Bratton offer the following conclusions: Polynuclears below 75 per cent.: If there is a leucocytosis, one may look for an old infection, well walled off; there may be an acute exacerbation. Usually there is a mild secondary anemia. Polynuclears from 75 to 80 per cent.: Indefinite; the history of the case and the patient should be considered. In their series of 184 cases, 32 had polynuclears from 75 to 80 per cent., 15 were abscesses, 11 acute suppurative appendicitis. Polynuclears, from 80 to 85 per cent.: The patient is in no immediate danger unless the total leucocyte count is low, suggesting a poor resistance. If the leucocytes are increasing, an immediate operation should be advised if the relation of the polynuclears to the total leucocyte count indicates a good resistance. If the leucocytes remain stationary or decline, the surgeon should rely on the physical signs in making up his mind when to operate. Polynuclears, from 85 to 90 per cent.: Look for a severe infection. If there is a proper leucocytosis, according to the chart, an immediate operation is indicated. Polynuclears above 90 per cent.: Virulent infection, grave prognosis. Twenty-five of their 31 cases above 90 per cent. had some form of peritonitis. Where there is no increase in the leucocytes, and the polynuclears high, little hope can be entertained for the patient from an operation.

Frequency of Cancer of the Cervix Uteri.—John A. McGlinn says that cancer is a disease of antiquity and is a disease which will eventually supersede all others in importance. If the present rates of increase in cancer and decrease in consumption are maintained, cancer will exact more deaths in the registration area of the United States by the year 1931 than consumption. He recently showed that out of a total of 140,088 deaths from cancer, the stomach and liver were the site of the disease in 36.4 per cent. and the female genitals in 14.7 per cent. The uterus is the most frequent organ to be attacked primarily in women. In the registration area of the United States one woman out of nine over thirty-five years of age dies of cancer. One woman out of ninety at all ages dies of cancer of the uterus. One person out of 162 of the whole population, male and female, will die of cancer of some part of the genital tract. Cancer has increased from 64.5 per 100,000 population in 1901 to 73.1 in 1907. That cancer is the most important lesion of the genital tract admits of no controversy. In 1907 cancer of the female genitals killed over three times as many women as abdominal tuberculosis; five times as many as venereal diseases; fourteen times as many as tumor; nearly twice as many as endocarditis; seven times as many as ulcer of the stomach; twice as many as cirrhosis of the liver; almost as many as typhoid fever; nearly twice as many as appendicitis; five times as many as were killed in all railroad, street car, horse and carriage, and automobile accidents. Cancer in general is apparently less common in negroes than in whites, although cancer of the uterus is more frequent. A table presented shows that the death rate was highest in those whose mothers were born in France and lowest in those having mothers born in Poland. It would seem that an admixture of the races lessen the frequency of the disease. He was not prepared to say that occupation bears any particular significance as to the etiology of cancer of the female genitalia. Another table shows that the age of greatest frequency is between forty-five and forty-nine (18 per cent.). Of 2,291 cases, 1,551, or 67 per cent., occurred between the ages of forty and sixty-four. It is generally stated that 90 per cent. of all cases of cancer of the uterus occur in the cervix. Cancer of the body of the uterus as a rule develops later in life than cancer of the cervix and has a longer duration. The length of life in cancer of the cervix is usually given as two years, while in cancer of the body it is thirty-two months.

Treatment of Epistaxis.—Beverley Robinson says that the essential thing to do in order to stop a too abundant epistaxis is to plug the nasal passages properly and effectively. This may be done by taking a strip of aseptic, absorbent cotton, such as comes in layers, and twisting it round and round, so that it becomes the size of the little finger; then with a good light fill the lower and middle meatus as far back as possible, on one or both sides of the nose, using a nasal speculum, and a director or stiff probe for the purpose. Postnasal plugging is rarely called for. When the epistaxis is slight, or moderate, it is as a rule unwise to attempt to stop it. Cold may be applied to the frontal region, or a little cold water may be snuffed up. Nature not infrequently allows bleeding from the nose as a relief from symptoms or as a protection from other troubles more important. Profuse nasal hemorrhage, arterial in character, comes from the artery of the septum, not far back from the anterior nares. A saturated solution of copper sulphate, applied one or more times by means of a cotton-covered probe, will probably cure it. This he considers the best local application to make and is superior to chromic acid, silver nitrate, or the electric cautery.

Journal of the American Medical Association, July 31, 1909.

The Ventilation of the Eustachian Tube.—A series of experiments on the ventilation of the Eustachian tube are reported by E. P. Fowler, in which experiments, he finds an increased intensity of sound from a tuning fork placed on the vertex during the act of swallowing. The following results were observed: "Opening the normal Eustachian tube by deglutition or by contraction of the tubal muscles causes increased perception for the sound of the lower tuning forks held before the nostrils as follows: With the ears open a marked increase was noted, with the ears closed by the finger (using care not to compress air in meatus) increase was noted; with one ear closed by the finger increase was greater in the other ear; with both ears closed by author's ear massage cups there was marked increase; with one ear closed by author's ear massage cups increase was more in cup ear; with both ears closed by author's ear massage cups (air in one rarefied or compressed), increase was noted in other ear; with both ears closed by ear massage cups, note is heard to increase more than with the ears uncovered, unless extreme quiet can be obtained. Opening the tubes immediately after autoinflation by Valsalva's method brings about a distinct increase in the sound perception. Opening the tubes after autodeflation by Toynbee's method or otherwise brings about a still greater increase. If one tube is blocked, the increase is noted during swallowing only on the patent side. If a long rubber tube is slipped over the shank of the fork, and its distal end placed in the nostril, results similar to those described may be elicited during tubal opening, but if the tubing is inserted into the external auditory meatus no change in intensity occurs. So much for the increase in sound during tubal opening as heard by air conduction through the Eustachian tube." The various cranial tympanic conditions of sound with the fork on the vertex are also given. The increase of sound during tubal opening here is accounted for by two main factors, one air conduction through the tube, and the other the increased bone conduction due to slight changes mainly in the drum membrane. Fowler presents some evidence for discussion that seems to indicate that during tubal opening there is a contraction of the tensor tympani muscle. In conclusion he describes an apparatus devised by him for ventilating the ears which he considers an improvement on the present method of home treatment for retraction of the drum. It consists of a rubber balloon attached to a nose piece. "If one nostril is closed and the nose-piece is fitted tightly into the other nostril, the patient may inflate the balloon by blowing into it through the nose. In the size I usually employ, a pressure of about 10 mm. of mercury is required to inflate the air-bag, and, no matter how much it is distended, the pressure within it will remain between 8 and 10 mm. of mercury. After inflating the balloon, the patient, without removing the nose-piece or releasing the opposite nostril, swallows, and repeats this act several times, or until the balloon has completely collapsed. At every deglutition both middle ears will be inflated. During deflation the air pressure in the balloon remains at about 6 or 8 mm. of mercury until the bag is deflated, when the pressure drops suddenly to zero."

Mongolian Idiocy.—Herbert E. Smead reports a case of this type of degeneracy and emphasizes certain diagnostic points, especially those between it and cretinism. He reviews the characteristics of this type and says that little is known of its causes, suggesting that the Mongolian features are possibly an example of atavism. They are evidently undeveloped children and their bodily development is retarded during infancy. As in all mental defectives, speech is late in developing—they may not talk until they are 5 years old. The degree of mental deficiency varies with the subject and in the border line cases they may acquire a fair degree of intelligence and education, but

they are always more or less mentally dwarfed. One might be misled into too favorable opinion by their generally amiable and cheerful disposition. They are imitative to a marked degree, and this he notes as another point of similarity to the Mongolian race. The vital prospects are bad. They are specially subject to many diseases, especially those of the lungs, and tuberculosis, from which many of them succumb before puberty. Pathologic anatomy gives little of importance and there is no specific treatment. Something may be accomplished by cultivating the imitative faculty and by good hygiene. Thyroid treatment is useless. At the approach of puberty special care must be taken with reference to the abuses of the animal instinct, as in all mental defectives. As Mongolians are often taken for cretins, according to his observation, and such mistakes may influence treatment, he gives in parallel columns the characteristics of the two forms substantially as follows: Characteristics seldom present before six months in cretins; in Mongolians present at birth. Cretins are dull and passive as opposed to the smiling, active, and imitative Mongolians. In cretins the hair is apt to be coarse and scanty, the skin is swollen and dry with fat pads above the clavicle. In Mongolians the skin is soft and fine, the hair straight and soft in early life. The skull is normal in shape in the cretins and brachycephalic in the other type. The eyes are horizontal with swollen lids and epicanthus absent in cretin, while in the Mongolian the eyes are oblique; there is no swelling of the lids and the epicanthus is present. In both the tongue protrudes, but in the cretin it is swollen. In these also the lips are thick and everted and fingers short and stumpy, while in the Mongolian the lips are natural and the fingers short and tapering, the little finger short and curving inward. Lastly, the thyroid is absent or atrophid in the cretin and thyroid treatment is beneficial if used early enough. In both of these respects the case is reversed with the Mongolian.

Pemphigus Neonatorum.—O. H. Foerster says that the possible identity of pemphigus neonatorum and impetigo contagiosa has not been given due prominence in English dermatologic literature. He goes over the recent literature and says that there "appears to be sufficient evidence at hand to warrant insistence on the proper recognition of pemphigus neonatorum as simply a bullous infantile variant of impetigo contagiosa and elimination of the confusing term 'pemphigus' when this affection is under consideration." Within the past six years he has had occasion to observe a number of instances in which midwives or others have communicated pemphigus neonatorum to infants or received impetigo from infants affected with pemphigus neonatorum. Although the disease is generally mild in character, it sometimes has an appalling mortality in infants. It is desirable, therefore, in his opinion, to have midwives report all cases occurring in their practice, as is now required in Prussia. At present no one bacterial organism can be credited as being the causative agent of the disease, though Almquist has named a special micrococcus as such and it has been isolated from cases in Manila by Clegg and Wherry. The *Staphylococcus pyogenes aureus* seems to be the one organism most generally found in pure culture. The same uncertainty seems to exist in regard to the bacteriology of impetigo contagiosa, and Potter ascribes the clinical differences between the two affections to the variations in the anatomy and physiology of the skin of the new-born and that of older children and adults. The treatment he has found most efficacious is the same in both; drainage of the vesicles or bullæ and exposure of the edges of the lesions, the entire base of which is freely anointed with 2 per cent. ammoniated mercury ointment, and individual isolation of the lesions with gauze and cotton dressings. For asepsis of the univolved surface the child is bathed in a warm permanganate solution and sponged with the same whenever the dressings are changed. External heat and full doses of brandy and strychnin are indicated as supporting measures if the disease is at all extensive.

Cerebellar Tumor Removal.—T. Diller and Otto C. Gaub have analyzed the statistics of removal of cerebellar tumors and find that the mortality of the operation has been notably reduced within the last few years. They also quote a letter from Dr. Harvey Cushing of Baltimore, giving his opinion based on experience of thirty cases, who thinks that with a certain method of operating the results may be as favorable as in the case of lesions of the cerebral hemisphere. He says: "It is my feeling that with a proper face-down position on a suitable operating table, with a skilled anesthetist and with a low operation with removal of the posterior half of the foramen magnum so as to get below the lips of the cerebellum and evacuate fluid before the dura is freely opened, these cases, contrary to the opinion that has been expressed by others, are as favorable, if not more favorable, for operation as lesions of the cerebral hemisphere.' The other side of the case has been shown by Knapp of Boston who, in his paper published in 1906, concludes from the study of 104 autopsies of brain tumor, that only four were anatomically accessible and presented enough clinical symptoms to be correctly located for the purpose of operation. A number of other authorities are quoted and the clinical and pathological record of their own cases is given with special detail. The operation seems to have been done according to Cushing's method for the most part, except that the patient was placed on his left side with a sand bag under the head. The operation was a success. The patient was relieved and has continued to do well. The features which seem to the authors specially noteworthy are given as follows: "1. The excellent recovery of the patient after the operation and his great improvement. 2. The position of the head, bent forward to the left on the chest and rotated to the right. This is against the common statement that in cerebellar tumors the head is drawn backward. 3. The very rapid subsidence of the optic neuritis following the operation. 4. The fact that the optic neuritis was greater on the right side—the side of the tumor—than the other side. 5. The great practical value of exposing the cerebellum over both sides; this, not only because it is frequently difficult to decide on which side a tumor is located, but because such an opening allows for far better manipulation and exploration of the cerebellum. Without this double opening the tumor in this case probably could not have enucleated. 6. The fact that considerable manipulation and even destruction of the cerebellar lobe is compatible with life. 7. The position of the patient on the operating table and the surgical technic are of the greatest importance. 8. The cardiac complication—the apparent development of an endocarditis which seems to have disappeared now." The tumor was situated in the right lobe, from one-third to one-half of which was cut away in removing it. Its size was about that of a hickory nut and the pathological diagnosis was myxosarcoma telangiectatum.

Pseudomembranous Anginas.—W. R. Murray gives case histories of three patients suffering from chronic pseudo-membranous faucial inflammation in which repeated microscopic examinations showed the presence of Vincent's spirillum and the *Bacillus fusiformis*. The bacillus has been described "as a spindle-shaped rod with tapering ends, slightly bulging in the center, usually straight, and from 6 to 12 microns in length. The spirilla, usually associated with the bacilli, are delicate spiral-shaped organisms, staining somewhat faintly, and varying considerably in length and in the number of twists or curves. Both organisms take the ordinary stains but are Gram negative. They are always found associated with other micro-organisms. Clinically, these acute lesions appear as a grayish pseudomembranous inflammation attended by necrosis; the necrotic area usually sloughs, leaving a penetrating ulcer, the floor of which is covered with pus which easily bleeds. The duration is from one to three weeks." In one of these cases the general health was good and the patient responded readily to treatment. In another, mild antiseptic spraying caused the disappearance of the exudate, but in the third the membranous deposits did not disappear until after the application of strong silver nitrate solutions locally, together with general tonic treatment. Clinically there was some resemblance to a mycosis in the local manifestations and some leptothrix were found in the smears. Whether or not the organisms as described by Vincent were the causative factor was not absolutely proved, but their continued presence would seem to justify the assumption that they had a causal relation.

The Lancet, July 24, 1909.

The Fate of Damaged Joints.—Richard Warren reports cases of injury, principally fractures, involving joints, treated in the massage department of the London Hospital. From a continuous series of nearly 400 cases taken for a period of about eighteen months, he concludes that, on the whole, the results are not bad, though certainly admitting of considerable improvement. If modern treatment be carried out, the outlook for fractures involving joints is less gloomy than some would have them believe. Unless cases are made to come and show themselves after treatment has ceased, one gets a false perspective of the results; one sees cases coming up week after week and month after month with very little signs of improvement. Cases doing well slip away, their treatment is shorter, and they leave less impression on the mind than do those stiff, squab, edematous, and utterly dreadful-looking ankles, as after Pott's fracture, which are constant visitors. With patience and perseverance,

however, these latter assume something of their normal proportions and are, at any rate in the majority of the cases, exceedingly useful and serviceable means of progression. He has found to his surprise the after-results much better than he expected. From the cases discussed the value of early movement and massage will be readily seen in improving and accelerating recovery of function. Massage and movement alone are not suitable from all fractures, though serviceable for a great many more than is commonly supposed. Certain fractures, *e.g.* Pott's fracture, must have some retentive apparatus to avoid displacement, not to produce immobility of the limb. In the treatment of fractures and allied injuries, as in a very large number of medical and surgical cases, two great and apparently opposing principles are used, viz., rest and exercise. In the past too much stress has been laid on the importance of rest in cases of injury, and it is largely to the French school that the credit is due of accentuating the importance of the other factors in treatment, movement, and exercise. For movement leads to power of function, and it is by proper appreciation of the importance of each of these principles and by correlating their application in practice that one could attain such perfection as is possible in this world of mortal men.

Painful Heels.—E. Reginald Morton reports the case of a woman, aged sixty years, who gave a history of pain and tenderness in the right foot and heel, which had got progressively worse during the past four months. At a later date the left foot and heel began to give trouble in the same way. Walking was attended with extreme discomfort. There was a distinct gouty tendency. A radiograph of each heel was shown. There was a development of a thorn-like process projecting forwards; one was more complete on the right than on the left side, thus conforming to the clinical history. There was also noted a thickening of the tubercle of the os calcis, an extra layer of bone being deposited thereon. He was informed by a New York surgeon that at least one of his colleagues looked upon these spiculas of bone growing from the os calcis as pathognomonic of gonorrheal infection. Steinhardt, however, admits the possibility at least of the condition being due to gout, rheumatism, and traumatism. The case reported was clearly not gonorrheal. Ionization was tried for a brief period, but the result was negative. The spicules were removed by operation, but the benefit obtained was slight and the patient was still unable to walk.

Purpura Hæmorrhagica, with Abdominal Crises Due to Intestinal Effusion.—G. Percival Mills reports such a case occurring in a boy, aged sixteen years, which was of particular interest in view of the causation of intussusception. Dr. Sutherland has quoted a number of cases in which this condition of intestinal effusion was found during a laparotomy for supposed intussusception, and shows that it has been not unnaturally regarded as the result of an intussusception spontaneously reduced. He brings evidence to show, however, that (a) all the symptoms of intussusception may be caused by intestinal effusion, and (b) that intestinal effusion itself is a cause of intussusception. The case reported presents a certain amount of evidence in favor of both these views. Before operation it was regarded as a chronic intussusception, and had only one patch of hyperemia been found a diagnosis of spontaneous reduction would probably have been made. He would be a bold man, however, who would assume the presence of twelve to fifteen intussusceptions, all of which had undergone spontaneous reduction, to account for the condition found. Consequently it must be admitted that intussusception may be closely simulated by multiple patches of intestinal effusion. Another point of extreme interest centers in an old scar which was found; its appearance strongly suggested an old intussusception, and the occurrence of intussusception and of intestinal effusions in the same patient is very suggestive.

Note on the Treatment by Radium of Lymphatic Obstruction (Cervical, Submaxillary, and Axillary) in a Patient Suffering from Filaria Nocturna.—The remarkable and rapid success that attended the use of radium in this case of filariasis prompts A. A. Warden to record it. Dr. H. Dominici outlined the treatment which he calls "Méthode du Rayonnement ultrapénétrant"; this consists of filtering the rays of radium through thick silver or lead plates. This treatment entailed no pain or discomfort and under its influence the several glandular masses rapidly diminished in size. Sir Havelock Charles first saw the patient and says that nothing could be done surgically, and medicine gave no hope. He calls attention to the beneficent influence of radium in these cases and says that if he were returning to the tropics he would equip himself with a working quantity of this element for use there.

Münchener medizinische Wochenschrift, July 13, 1909.

The Chantemesse Ophthalmoreaction for Typhoid Fever.—Becker reports his experience with the ophthalmic reaction for typhoid fever. He first standardized his extract on rabbits and also by testing it in varying doses on patients who did not have typhoid. He found that the dose which would produce no reaction on his controlls was 1-20 mg. At this dose the reaction was also negative in several patients who had had typhoid some years previously. An existing conjunctivitis was increased by the toxin. In eight cases of typhoid convalescence, of one to two weeks, the reaction was positive. The only cases in which the reaction was negative were two of supposed typhoid in which bacilli were found in the blood, but were not definitely identified—possibly paratyphoid bacilli. Of eight acute febrile typhoid cases the reaction was positive in seven, negative in one. One case gave a positive reaction to both typhoid and paratyphoid extracts. The author cites the results of other observers who had not been able to get constant results with this reaction and states that their error probably consisted in the failure to standardize their toxin on healthy patients before beginning the experiments.

Deutsche medizinische Wochenschrift, July 15, 1909.

Tubercle Bacilli Not Demonstrated by the Ziehl Stain.—Liebermeister has made a study of the form of tubercle bacilli and bacillary granules described by Much as not demonstrable by the Ziehl method of staining, but by a prolonged Gram stain. His conclusions are: (1) The tubercle bacilli contain granules, as a rule, which are so resistant that they may remain even after it is no longer possible to demonstrate the bacilli. (2) Not only tubercle bacilli but many other bacteria contain granules; it is, therefore, possible to confuse tubercle bacilli granules with other forms. (3) The bacteria granules are exceptionally resistant to chemical and physical influences. Their presence gives no information as to the virulence or power of growth of the bacteria which contain them. It is not justifiable to consider the granules as a special form of tubercle bacillus. The author does not consider that it is proven that the free granules and especially the "dust-like" granules are of diagnostic value, as they are so easy to confuse with other organisms. On the other hand, gram-positive bacilli and granulated bacilli are of value in diagnosis if the presence of other organisms can be ruled out.

Indications for Forced Labor in Diabetes.—Offengeld says that pregnancy and diabetes affect each other very badly, but that we are able to influence the results by proper therapy. The so-called mild and medium cases must be treated according to the common principles of diabetes, allowing an increased amount of food on account of the requirements of the fetus. In the severe cases, through the influence of the pregnancy, the disease taking on a malignant character, due to the requirements of the fetus, the transmission of its metabolic products to the mother, and the action of the placental ferments, interruption of pregnancy may be necessary. This is indicated by rapid decrease of carbohydrate tolerance, loss of weight, and increase of subjective symptoms. Acidosis alone does not indicate it, as this is often a constant feature and is associated with nephrosis (albuminuria with casts). In multipara the history of the course of former pregnancies and convalescence are of value. Though coma may come on very suddenly, it usually gives prodromal symptoms, as protracted acidosis and increase of ammonia excretion. When coma has appeared it indicates an event in which the child always dies and the interests of the mother demand the most rapid delivery possible. Diabetic women are no more predisposed to infection or hemorrhage than the healthy. If possible, the delivery must be performed without anesthetics.

Hyperemia of the Urethra by Hot Sounds.—Porosz advises the treatment of urethral strictures on the principle of the Bier hyperemia. He states that the old treatment of local heat by poultices was simply a method of producing hyperemia, and he applies this principle to the urethra. For this purpose he has devised a special sound, hollow, and divided into two compartments, connected at the tip so that hot water may be allowed to flow through it.

Book Reviews.

Military Hygiene. By Valery Havard, M.D., Colonel Medical Corps, U. S. Army; President Army Medical School. New York: Wm. Wood & Co., 1909.

This work is a manual of hygiene and sanitation primarily for army medical officers, but also for the line and staff, all of whom must of necessity know something of this subject. The author has taken up the subject with the selection of recruits and then treated every matter which would modify their health and efficiency. Special attention has been given to the newer things developed in the last few years, particularly the infections and how to avoid them. A work of this kind must, of course, hold to the old unless it is conclusively proved to be false, but when there is a difference of opinion on any minor subject it would have added to the interest of the book had the opposing view been stated. In recommending wool for underclothing, the author omits to mention the fact that hygienists are gradually coming to the opinion that wool should never be next the skin and that better health is obtained from the use of cotton or linen of thickness appropriate to the season. Similarly, in recommending wool for the tropics, the author ignores the contention of those who declare that under no circumstances should anything but cotton underclothing be worn. In adopting Chittenden's low nitrogen diet, the author will doubtless be attacked by those physiologists who hold that Chittenden is wrong in his premises and that his theory is dangerous.

The newly-discovered effects of light are admirably treated, though the author is mistaken in stating that no statistics as yet show that blonds in light countries suffer a greater morbidity or mortality than the brunets who are sufficiently protected by pigments. In praising cold bathing in the tropics, it should have been stated that East Indians frequently advise tepid baths as safer and more comforting. The several forms of heat stroke are not distinctly differentiated, and no mention is made of the cramp-like cases of fire-rooms now bothering the naval surgeons.

In these and other minor matters of controversy it would have been better had the author stated the other side and let the reader form his own judgment by weighing the evidence, or hold it in abeyance until the matter may be settled by some future observations. In the larger and most important matters, however, on which there are no serious differences of opinion, the work is excellent.

Uber die Behandlung der Geburten bei engen Becken. By Dr. E. Scipiades, Assisten zu Tauffer's Klinik in Buda-Pesth. Berlin: Verlag von S. Karger, 1909.

This publication represents the views entertained by the members of Tauffer's clinic in the treatment of labor in the presence of contracted pelves. Their observations are based on a series of 6,788 cases which were delivered during a period of ten years in this clinic, among which 14 per cent. showed an abnormal narrowing of the pelvis. Of this number 76 per cent. were delivered spontaneously and in the remaining 24 per cent. operative interference was necessary. Th writer is therefore inclined to await the spontaneous termination of the labor, particularly where the patient has not been under previous observation. In order to increase the number of spontaneous births it is strongly urged that in every case where the fact of a contracted pelvis is known before the advent of labor, the size of the child's head be kept as small as possible by careful dieting of the mother, as advised by Prochownik and by the "starvation method" advocated by Oertel and Ebstein. Where labor is present and the head engaged, Scipiades recommends a trial of the procedure of Hofmeier, by which it is sought to press the head through the pelvic canal by external manipulation. Where this fails forceps is indicated. Cesarean section does not seem to find so much favor with the writer as with others, and he is rather inclined to the performance of hebosteotomy, a contention which will scarcely meet with favor in many quarters. As the book is based on a large amount of clinical material which has been very carefully studied, the conclusions will certainly attract attention in obstetrical circles.

Handbook for Attendants on the Insane. Fifth Edition, Revised and Enlarged. Thirty-third thousand. Published by the authority of the Medico-Psychological Association Chicago: W. T. Keener & Co., 1909.

The Medico-Psychological Association of Great Britain and Ireland stands sponsor for this book. Its first edition appeared in 1885. It has been used considerably in the United States, in hospitals for the insane, and the present edition, the fifth, is published here. The original aim of the book was to give asylum nurses of the insane "such simple notions of the body and mind in health and disease, such instructions for the management of those maladies with which they are usually brought in contact, and such rules for their guidance in matters of everyday experience as will enable them to do their work with greater intelligence and watchfulness." The new edition shows that the scope of the book has been considerably enlarged. This was made necessary by the extension of systems of training and a demand for advanced teaching. It is used very extensively in Great Britain as a textbook, and comprises a syllabus of questions for examination for the British Certificate of Proficiency in Nursing the Insane. Only two pages are devoted exclusively to attendance on the insane in private houses.

The Dissociation of a Personality, a Biographical Study in Abnormal Psychology. By Morton Prince, M.D., Professor of Diseases of the Nervous System, Tufts College Medical School; Physician for Diseases of the Nervous System, Boston City Hospital. Second Edition. New York, London, Bombay, and Calcutta: Longmans, Green & Co., 1908.

The demand for books on the mental treatment of nervous disorders during the past two years has been as great as, if not greater than, the supply. Physicians have interested themselves in the subject more and more and have tried to keep pace with the clergy and other laity both in its study and by contributions to its stream of literature. It must be gratifying to Dr. Prince that his book has been sufficiently popular to justify a second edition, for while dramatically interesting it is hardly suited to the laity. Indeed, should it circulate among the neurotic it is calculated to do considerable harm. The rôle played by subconscious states in normal minds is a great problem of psychology. In certain individuals of unstable make-up the mind may be so disintegrated that several subconscious states may be formed in the same individual, each capable of more or less independent activity. "The Dissociation of a Personality" is an elaborate report of a single case of this nature. The subject had three personalities, and the writer has described them in great detail as to their condition and genesis and their psychological relationship to one another. There is also depicted a biographical account of each personality respecting its ability or failure to adapt itself to circumstances and environment. The second edition of this interesting book presents some further data on the phenomenon of sudden conversion and a less elaborate account of an additional case of non-religious type, the findings in which, the writer states, confirmed those obtained in the original case. The student of functional nervous disorders will find his knowledge of conscious and unconscious processes markedly increased by a careful perusal of this book, and thus obtain material aid in intelligent therapeutics. It is a distinct contribution to psychopathology.

Legal Medicine and Toxicology. By R. L. Emerson, A.B., M.D. (Harvard), Member of the Massachusetts Medico-Legal Society, Formerly Instructor in Physiological Chemistry, Harvard University Medical School, and Assistant in Clinical Pathology, Boston City Hospital. New York and London: D. Appleton & Co., 1909.

Although from its very nature the practice of medicine is intimately associated with the administration of the laws, and physicians very frequently are called upon to assist in deciding questions of justice or to maintain their own rights, it is unfortunately true that as a class they are not as well informed in this branch of knowledge as the general versatility of the profession would lead one to expect. Matters making even a modicum of medicolegal learning of the greatest use are constantly arising in everyday practice, and emergencies actually demanding it are likely to occur at any time. There is no lack of satisfactory treatises on the subject, but the present volume is one that is well qualified to serve as a guide on all ordinary occasions, and it may be warmly commended to practitioners both of medicine and law. It comprises three sections of about two hundred pages each, the first being devoted to forensic medicine proper, the second to toxicology, while the third is composed of extracts from the laws of the various States referring to the practice of medicine. The treatment of the several topics is excellent and the author's style most agreeable, so that the book may well be regarded as one for perusal and not merely as a work of reference. The only criticism that suggests itself is that, in some instances at least, the methods for carrying out the tests for the recognition of poisons are not given in sufficient detail to serve as a working guide, while, on the other hand, if not intended to serve this purpose the space devoted to them is needlessly great. In all important respects, however, the book is very satisfactory, and should prove a useful and trustworthy exposition of this most important subject.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-seventh Annual Meeting, Held at Belfast, July 23—31, 1909.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

Friday, July 23—Monday, July 26.

THE annual meeting opened at Belfast Friday, July 23, and continued throughout the following week, the excursions closing the proceedings on Saturday, July 31. The first three days were occupied, as usual, with the annual general meeting, and the representative meeting. There was a service in the Cathedral on Sunday, and on Monday the annual conference of Secretaries of Divisions and Branches, as well as a continuation of the representative meeting. At this Dr. J. A. Macdonald presided, and the discussion on the medical inspection of school children was resumed, and much said as to the duties of school nurses. There seemed to be a general opinion against children found defective at the inspection being dealt with in institutions which come under the category of public charities, and it was urged that until the report of the Royal Commission on Poor Law is issued any attempt to draw up regulations for the treatment of school children would be inopportune, as there is little doubt that considerable alteration in the law will be recommended. A resolution was adopted that in a district with a scanty population provision for the treatment of those children in need of it should be made by the recognition of private practitioners' surgeries for the purpose, and that at the public expense. In towns of considerable population it was resolved that private practitioners should be permitted to discharge the duties of school clinics. A draft of model rules for district nurses was approved.

The report of the committee appointed to inquire into the treatment of ophthalmia neonatorum was considered. Several resolutions were adopted on the relations of the profession to public health authorities, after a pretty full discussion. It seemed to be generally agreed that the minimum salary of £250 should be paid for an assistant medical officer of health who devoted all his time to the duties of his office; that, owing to the multiplicity of duties placed upon a medical officer of health by recent legislation, in future appointments of the kind should be on condition that all the time of the officer should be devoted to his duties, he being debarred from private practice, except as a consultant; that he should be adequately paid, and, if necessary, small districts should be grouped. On the other hand, it was held that these officers should be protected in the discharge of their duties, should not be liable to capricious dismissal, and should be participants in any scheme of superannuation in their districts approved by the Local Government Board.

The work of medical inspection of school children was also discussed, and it was resolved that the minimum salary of such officials ought to be £250 per annum.

A further resolution was passed to the effect that the time had come when the association might take into consideration the drafting of a scheme for a public medical service, embracing the Poor Law Service, providing dispensaries, school clinics, friendly societies, and sick clubs.

Tuesday, July 27.

On Tuesday there was a large attendance at the general meeting, when the new President, Sir William Whitla, was formally inducted by the retiring President, Dr. Sinclair White, who had undertaken the work on the decease of the late Mr. Simeon Snell of Sheffield, whose death had occurred during the year. In introducing his successor, Dr. White said Sir. Wm. Whitla's eminence in therapeutical science was a guarantee that he would uphold the dignity of the office to which his colleagues had called him.

Dr. Macdonald was elected as Vice-President of the association in recognition of his services as chairman of the representative meetings since 1906.

In the evening the hall was crowded by a brilliant gathering to hear the new President's address. The foreign and Colonial delegates were in full force, and were greeted with much enthusiasm when they replied to the address of welcome given to them. The Lord Lieutenant, with the Countess of Aberdeen, attended, and when they entered were received with great cheering.

President's Address.—Sir WILLIAM WHITLA delivered this address, taking as his title: "A Survey of the State of Medical Education." He said the present state of medical education was most unsatisfactory. A medical curriculum planned forty years ago was now entirely out of date; for in 1869 bacteriology was scarcely dreamt of, medicine and surgery were in a rudimentary state, contrasted with their present condition; sanitary science was practically non-existent, and it was possible to obtain a degree or diploma in medicine in less than a three years' period of study, while at present the stringent regulations of the General Medical Council made it impossible for the student of medicine to obtain his qualifications to practise until after the lapse of a minimum period of five medical years. Under the existing regulations the brain of the student failing to expand in assimilative power with the growth of advancing science, they arrived at the crux of getting two pints into the one pint pot. The effect of this attempt to achieve the impossible was seen in the fact that the average time now spent by the medical student in obtaining his degree or diploma was not the minimum of 57 months but of almost 84 months. One of the evils arising out of the present system was that a considerable proportion of students, after failing to pass in the preliminary subjects, proceeded to attend the classes in the advanced subjects and so paralyzed their capacities for obtaining anything like an efficient training in the subjects whose practice was to become their ultimate life work. After more than a quarter of a century's experience as a hospital teacher and examiner, embracing a practical acquaintance with the working of three universities in the United Kingdom, he felt constrained to believe that in the sending out of men qualified immediately to enter upon the routine practice of their profession, they were, in some respects at least, behind the results obtainable in the old days of apprenticeship. The preliminary and intermediate periods, amounting to three out of the minimum of five years, must be shortened, and the clinical period of study increased, if they were to train most efficiently and turn men out of their teaching institutions properly equipped for their serious life work. An enormous aid to the readjustment of the curriculum would be a compulsory examination in experimental physics and chemistry at matriculation. There was a growing conviction that a prolongation of the period devoted to clinical studies could be achieved only by a radical change in the method of teaching the entire group of preliminary and scientific subjects. Professor Starling had said "that from the very commencement of his medical curriculum the work of the student should be directed, every scientific subject which he studies, whether it be chemistry, physics, or physiology, should be considered only in its bearings on his future work as a medical man." The President suggested that these words should be written in letters of gold and set up in the retiring room of each teacher of the preliminary and intermediate subjects in our universities and medical schools, when soon they would cease the lamentable fiasco of the attempt to make every medical student an accomplished physicist, an analytical chemist, an

experimental physiologist, a practical botanist, and an expert zoologist as these phantoms dangled before his mental vision while he was already far advanced in putting in a vacant perfunctory attendance at his final classes, or while he was absent-mindedly sauntering about the externe department or wandering aimlessly through thhe hospital corridors. Beyond the shadow of a doubt the time had fully come when a general and complete overhaul of the medical curriculum in all the universities and in every medical school in the United Kingdom was urgently necessary, and there could be little doubt that the reconstruction must be carried out upon the lines indicated by Professor Starling.

Wednesday, July 28.

On Wednesday after the council meeting the sections began their work. After their morning sitting came the **Address in Medicine,** which was delivered to an appreciative, large audience by Dr. R. W. PHILIP of Edinburgh, who is Physician to the Royal Infirmary and the Victoria Consumption Hospital in that city. This address was the chief feature of the day, and one of the chief of the week. The subject was "Tuberculosis." He took a cheerful view, as the cause had been discovered, and thought they might look forward confidently to the time when it would cease to be. Everything, he said, pointed to its final disappearance among the nations which regard public health as an integral part of civilization. Was not the disease, he asked, the expression of ill-formed civilization? It was introduced by ignorant, unthinking mankind, and it was for thinking and educated mankind to expel it. The realization of its frequency in childhood was the first step towards its timeous recognition. To remove the weed at the seeding stage was easier than when it had grown to a tree. The children must be carefully scanned by the family doctor before they were seen by the school inspector. In conclusion, Dr. Philip described a city built today *de novo* in accordance with hygienic and physiological law. He would have the structure and arrangements of its houses to be the first consideration. Sunless, airless dwellings should not be possible. Every apartment should have the maximum of sunlight and windows should fulfill their other function as well, viz., to let in air. Every child should be trained to regard the dual function of windows as vital to safety. The nursery, especially, should be bathed in air and sunshine. The schoolroom should be an object lesson in hygiene. None should be permitted in which ventilation was not largely associated with open windows. In fine weather much school work should be done out of doors. The streets of this city should be wide; open spaces should abound in it. Crowding in dwellings, offices, work-rooms, factories and all meeting places should be criminal. The housing of cattle should be regulated as strictly. In such a city the soil to suit tubercle would not exist, and, consequently, tubercle would be unknown. It need never appear.

Visits to the harbor, docks, factories, and other sights in Belfast filled up the time of many on this and other days. In the afternoon of this day the great attraction was the garden party given to the members and friends by the President and Lady Whitla. The Lord Lieutenant and Lady Aberdeen were present, and a great concourse of the members, as well as residents of the city, attended with their lady friends.

In the evening the annual dinner took place, and while it was in progress a ladies' reception was given by local members at one of the theaters, where a number of Irish plays were produced by members of the Ulster Library Theater. The exhibition of surgical instruments, drugs, etc., open each day, was visited by many.

Thursday, July 29.

On Thursday morning the breakfast given by the National Temperance League, as for several years past, was the first function. After this the sections again occupied the morning, though during their sitting, and later in the day, also, there were other attractions for those who shunned the scientific work. An inspection of flax-spinning works, another garden party, given by Sir T. and Lady Dixon, a drive into County Down, inspection of distilleries, and a reception at the Royal Victoria Hospital, and even a cricket match, afforded ample variety. Then in the evening the Lord Mayor gave a reception in the City Hall, academic dress or uniform being expected.

The Address in Surgery.—Professor BARKER of University College, London, delivered this address, in which he traced the progress of intestinal surgery from the time of Lister, during which period he had taken his part in it. He did not look on the improvements made as due solely to asepsis nor to any increase of manipulative skill. He rather attributed it to clearer views of the vital processes involved in all abdominal lesions; these resulted from closer observation of cases and the careful sifting of experience as well as the assimilation of the progress made in anatomy, physiology, pathology, and other branches.

Honorary Membership for the Countess of Aberdeen.—A special feature of this day's proceedings was conferring upon the Countess of Aberdeen the honorary life membership of the association, in recognition of her great work as President of the National Health Association of Ireland, and the splendid campaign her Ladyship has carried on against the spread of phthisis. Mr. Owen presided, and pointed out that Lady Aberdeen would be the only woman made an honorary member in the history of the association. At a reception in the evening, held by the Lord Mayor in the City Hall, the Earl and Countess were present, and nearly 2,000 guests. The Lord Lieutenant has also been present at many of the functions, and thereby contributed greatly to the success of the meeting. Everyone in the city is talking of the help he and Lady Aberdeen have given. At the dinner his Lordship made a most felicitous speech, in which he referred to the honor about to be conferred on Lady Aberdeen, and said in a sense he was ahead of her, as he was made an honorary member at the Montreal meeting, where he received the association in the capacity of Viceroy.

At the ladies' reception, the Countess, having been asked to tell something of the work she inaugurated 2½ years ago, said the Women's Health Association had not been established for the anti-tuberculous movement alone, but was founded to rouse the women of Ireland to a sense of their peculiar responsibilities in regard to the health of their nation, and of their homes, and show them how much they could do to bring up a strong and vigorous race, and to combat the special diseases that were injuring the Irish people at large. The work was divided into three sections: (1)Anti-tuberculous; (2) combating infant mortality; (3) school hygiene. Her Ladyship then described the Tuberculosis Exhibition, which had been pronounced a great success, 44,000 persons visiting it in its fortnight's stay at Belfast. It had visited fully 80 districts in Ireland, enormous crowds attended it, and the eagerness with which the people asked for guidance was most pathetic. When it went to any locality a branch was usually the result. Here in Belfast the work had been splendid, and four babies' clubs had been formed—the first of the kind in the United Kingdom. A tuberculosis class had also been formed under the care of Dr. M. Andrews, and the result of all these agencies was most encouraging. A number of views, illustrating the features of the anti-phthisis crusade, were then thrown on the screen and explained by her Excellency.

Compulsory Notification.—Another occasion on which the Viceroy and Lady Aberdeen displayed their interest in health matters was in attending some of the sections in which these questions were under discussion. One of

these was when the Lord Lieutenant proposed a vote of thanks to Dr. L. Parker for his address on hygiene, and afterwards took part in a discussion on notification, when Dr. Scurfield of Sheffield gave an account of the operation of notification of consumption in that town, where it has been compulsory since 1903. The Viceroy said he should like to congratulate Sheffield on being so enlightened. At this discussion there was, however, one note of opposition among the 6 or 7 speakers who supported compulsion.

Dr. Walter of Dublin denounced any such interference with the liberty of the subject, and compared the methods of notification to those of the Holy Inquisition, which, he added, were too late in the 20th century.

Sir C. C. Cameron replied, and asked what the opponents proposed, for something must be done, and nothing else practical had been proposed. For 2 or 3 years they had some voluntary notification in Dublin, and nobody objected. Sir J. Byers replied for Belfast, and hoped as the result of the discussion the Health Committee would make an advance. Some other speakers supported notification, one of them calling the talk about the Inquisition nonsense, a verdict repeated in all directions outside after the meeting.

SECTION OF MEDICINE.

Wednesday, July 28—First Day.

Professor James Alexander Lindsay, President, in the Chair.

Discussion on Angina Pectoris.—Sir Clifford Allbutt, K.C.B., proposed in opening the discussion to ascertain precisely what was to be discussed, and in what terms. He urged concerning this malady that precision both of terms and of substance was especially needed, for no disease had been more obscured by factitious notions or more confused by false analogies and erratic conjectures. Yet in all medicine there was no disease which presented a clearer image to the observant eye, nor one more conspicuously detached from the clinical jungle. If its characters were confused they had been confused by equivocations; if its type blurred it had been distorted by counterfeits. If angina pectoris were looked at simply, without prepossession and with discrimination, its features came into focus and the type took fairer definition. On the threshold the speaker found himself confronted by sophists who said bluntly that angina pectoris was not a disease, but a symptom or "symptom group"; it was here, indeed, that the sophistry began, for this argument was but a play of words. "A symptom" angina pectoris certainly was not, for it was manifold; a symptom group it was no doubt, or rather a symptom process, or procession. Now a symptom group, or procession of symptoms negative and positive, which recurred in mankind with fair uniformity, must be due to causes correspondingly uniform. That genuine angina pectoris might occur with the heart, lungs, and kidneys intact was at last reluctantly admitted by physicians who had studied the data; and if so the essential, as apart from contingent causes, must lie outside these organs. He will divide angina pectoris into angina minor and angina major, and the symptoms of the two degrees were compared. "Pseudo-angina" he dismissed as pseudol diagnosis, and relegated these cases to the Vaso-vaga class of Gowers. Vascomotor oscillations commonly occurred in angina pectoris it was true, and in two main but incidental relations: first, as determinants, when by changes of blood pressure attacks were provoked or mitigated; secondly, as consequences of acute impressions reaching the nerve centers by afferent paths. The speaker would proceed to appreciate the current hypotheses of angina pectoris, pointing out the diversity of these irreconcilable and often mutually destructive explanations. He again advocated his own interpretation, first published in 1894, which had been fully accepted by Josué, in a paper published last November. This interpretation was that the origin of angina pectoris was not in the heart but in the suprasigmoid portion of the aorta; that the oppression of angina minor was seated in this place; and that in angina major the referred pains still originated here, but, as in the degrees of their severity they forced successive centers, they radiated over more and more extensive areas. That, as concerns fatality, angina pectoris, neither in its minor nor in its major forms, was directly fatal; that indeed in many, perhaps in the majority, of major and minor cases taken together death, if it occurred, was due to cooperating causes; that in a large number of cases, whatever the issue of cooperating lesions, such as valvular or myocardial disease, the anginous lesion healed, or, at any rate, the symptoms ceased, and, furthermore, that not a few cases of angina pectoris, even of the major variety, ended in complete recovery; that when death was directly attributable to the angina it was due to vagus inhibition, such as was prone to happen, for example, in surgical operations about the root of the lungs or the brachial plexus, or to be induced by some other intense peripheral irritation, as in the genitalia. Finally, that, although a sound heart might be inhibited to the point of death, this very rarely happened, and that in nearly all cases in which the heart failed to disengage itself from the inhibitory interference the myocardium, whether by coronary disease, by toxic influence, or otherwise, was previously unsound.

Sir Lauder Brunton could not accept the view that the aorta was the only source of aortic pain. He could not think that the distinction of angina major and minor was a sound one in that they were not degrees of the same disease. Pseudo-angina, as usually termed, was, he thought, a real clinical entity. It occurred in young persons, and though the pain was often extremely severe, yet it did not cause death, and was not relieved by nitrites. He alluded to the difficulty of examining the sensibility of the heart. Experimentally he could not admit that the cardiac plexus was purely motor, as had been maintained. Mere distension of the serous covering of an organ was not a cause of pain as seen in the bladder and intestine; not until the muscular fiber began to contract was there pain. So he thought the distension of the serous covering of the aorta was an unlikely source of the pain. He still held to the view that cramp of some of the muscle-fibres of the heart was one cause of the anginal pain, and that it was largely due to the excessive work of the heart under excessive resistance. He thought angina a symptom of many diseases. Some indication of the site of the cause might be derived from the seat of the pain; thus, in many cases the pain was referred not to the sternum primarily, but to the apical region of the heart. Patients might have freedom from pain for many years, but this did not certainly mean abolition of the cause of the pain, and in these he thought the tendency to sudden death was greater than in other persons. In pseudo-angina the treatment was tonic, as in a neuralgia, but in true angina it was rather repressive, avoiding violent exercise, with moderation in diet, and the exhibition of nitrites.

Dr. W. Osler thought there was a group of cases that corresponded precisely with that described by Sir Clifford Allbutt, as in syphilitic aortitis, arteriosclerosis at the root of the aorta in old people, etc., but this was only one group. There was a group of cases in which there was disease of the coronary arteries alone, not a trace of any disease in the aorta. There was a third group of cases in which neither the coronary arteries were diseased, nor the root of the aorta—those cases were exceptional. He himself had more belief in the intermittent claudication theory than in any of the other prevalent hypotheses, although it did not fit every case.

Dr. W. K. Hunter referred to Francois Franck's experiments on the effect of irritating the inner surface of the aorta just above the valves in causing constriction of the pulmonary vessels. He described the clinical facts in a case that had been under his care in which, although there was aortic regurgitation the systolic blood pressure ran very high during the attacks, and the pain was greatly relieved by nitrites.

Dr. W. Gordon had found that in his cases the blood pressure was higher in the recumbent posture than in the erect, and he connected this with the occurrence of some attacks of angina during sleep. He pointed out that it was not easy always to recognize dilatation of the heart, especially of the right heart, when the patient was in the recumbent posture.

Dr. John Haddon referred to a case of angina associated with aortic aneurysm, and advocated reduction of body weight in cases of angina.

Sir Clifford Allbutt in reply said the higher in the aorta an aneurysm was the less likely it was to cause angina. He thought pseudo-angina could not be looked upon as a group of cases of angina. He welcomed the view expressed that aortitis was competent to produce angina pectoris, and he thought a definite procession of symptoms could not have two opposite causes. He thought that it was the pull on the tender parts of the root of the aorta that was the cause of the pain. There was, he believed, no sensory ganglionic appartus in the heart.

Papers were read by Dr. D. W. Samways (Mentone) on "Some Misconceptions Concerning the Riviera," and Dr. W. Gordon (Exeter) on the "Influence of Soil on Phthisis."

Thursday, July 29—Second Day.

Discussion on the Medical Aspects of Athleticism.—Dr. Tyrrell Brooks of Oxford, in opening this discussion said that athletics were as old as history, but physical training was modern. It was his experience that the most vigorous undergraduates came from the schools whose athletics were of the more strenuous type. From an enquiry of the medical officers of the principal public schools as to the influence of athletics on health extending over twenty years, only five deaths were on record. These were almost exclusively from surgical injuries sustained during games. One, however, was from asphyxia, due to regurgitation of food during bar exercises undertaken shortly after a meal. From Oxford during the same time there were two deaths during athletics on record, and one of these was in a case of aortic valvular disease. Among the same boys during the same time, on the other hand, four cases of sudden death occurred quite apart from athletics. Of the organs likely to be damaged from athletics in excess the heart was the chief. Valvular damage, due to exertion, was very rare, but it was to be remembered that slight dilatation of the heart was difficult to estimate. Excessive smoking, alcoholic indulgence, gluttony, or sexual excess might produce exactly similar effects in perversion of the heart's action. The toxins produced during febrile attacks had also a similar deleterious action. It was almost certain that with the natural resilience of the heart was so great in boyhood that mere muscular exercise could hardly seriously damage the heart. Precaution to minimize the dangers arising from athletics during school life included an entrance physical examination, careful observation of the younger boys in the ordinary games, and an ample interval between the previous meal and active exercise. Cases of sudden death in boys were indeed in large proportion due to taking violent exercise after a heavy meal.

Special care in permitting active exercise after convalescence from acute illness was also one of the more important precautions. Reference was made to the researches of Dr. John Morgan on the life history of men who had taken part in university boat races, showing that their longevity and physical activity were above the average. In discussing the matter of long school runs he would forbid them to asthmatics and those liable to undue dyspnea, but if only sound boys were allowed to take part, and if preliminary training were enforced, there was, he considered, little fear of any harm resulting. He asked if the profession was not inclined in these matters to sacrifice the interests of the race to the interests of the individual.

Dr. Clement Dukes said that terrible catastrophes did occur at times from undue athleticism, and that these were quite preventable. The harm of the old idea that young boys of nine or ten and the older of nineteen had to undertake the same exercise was emphasized. The Greeks aimed at, and attained, by their well-regulated physical training, the highest perfection of the human form, which also influenced the moulding and elevation of the mind. The strength and wisdom of the next generation depend upon the mental and physical development of the present, for the intellectual value of exercise is as great as its physical value. Athleticism is the "intemperance" of physical exercise, which is injurious to the not fully-grown body. Physical examination and medical direction are necessary to avoid this, so that the feeble may be strengthened by well-regulated exercise, and the strong not injured by unwise and prolonged exertion. He especially alluded to the effects of excessive football and running. The short, quick run was apt to cause rapid mischief to the heart, which as rapidly disappeared; on the other hand the long runs were apt to produce permanent damage to the heart by subacute or even chronic dilatation. But for full grown men the short, quick run was the more harmful. He considered an interval of at least an hour between a meal and active exercise was imperative. The effect on the ability to take violent exercise and coldness of the weather was pointed out. Details of the apparent serious consequences of excessive running were given. The former evil results of long runs at Rugby, owing to precaution now in force, were a thing of the past.

Sir Clifford Allbutt referred to the blood pressure observations recently made at Cambridge bearing on the effects of athletics in the young adult, an account of which was to be published in the autumn. The only serious results observed during those observations were in those who during the previous few months had been the subject of an acute infectious disease, especially a bad cold.

Sir Lauder Brunton thought the duty of medical men was to do the best for the race and for the individual, and he held that the rules lately drawn up by the medical officers of public schools would go far to attain this. He thought that regulated athleticism should begin in the preparatory schools. The ideal training for youths was probably a combination of the physical exercise methods and games—such a system as is at present carried out in the University of Pennsylvania or in the schools at Berne. He advocated the establishment in the schools of this country of the office of games-master, appointing men of social standing similar to that of the boys.

Dr. Anthony Traill, the Provost of Trinity College, Dublin, referred to the question of the introduction of Swedish drill into the schools of Ireland, and to the question whether it would not be necessary to institute medical examination of the children before such were commenced. The whole matter he considered turned in regard to the elementary schools on proper feeding, which did not at present exist in the Irish primary schools. Physical occupation, as carpentry, had, he believed, a strong influence on physical, as well as on intellectual development. Statistics from Trinity College, Dublin, showed that the majority of those taking fellowships and scholarships were athletes. The effect of physical exercise on moral states was discussed.

Sir James Barr said the more hazardous the game the better for the development of the character of the individual. The heart could only be strained by the stress that itself produced. The importance of vital capacity of the chest in severe physical exercise was emphasized.

Dr. Olive Riviere referred to heart strain as the result of holiday excursions for boys. Examining seventy-two boy scouts of the elementary school class he had found that some thirty-seven showed evidence of dilatation. Every boy scout should be medically examined, and the conditions of their existence supervised.

Dr. Gordon Gullan advocated the maintenance of the system of school games to the exclusion of any share of the system of compulsory physical exercises or gymnastics.

Dr. W. G. Tyson urged a continuous interest in athletics, the teaching of common laws of health in the public elementary schools, and the continuance of physical exercises in the individual throughout life.

Dr. W. R. Kennedy referred to the question of pulmonary hemorrhage in athletes due to obstruction to the blood flow in the right heart, and to toxemia, probably of gastrointestinal origin, the former depending largely on heart dilatation, for which rest and reduction of diet were imperative.

Dr. Tyrrell Brooks and Dr. Clement Dukes replied in general terms.

Dr. P. Dempsey showed a case of argyria following on treatment for gastric ulcer.

Professor Benjamin Moore demonstrated a new method of administering oxygen so as to give a known quantity of the gas.

Papers were read by Dr. Olive Riviere on the effect of cardiac strain incurred in a party of forty boys in a school excursion, and by Dr. Frank C. Eve on a case in which glycosuria was only to be inferred from the presence of gas and bacilli in the urine.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Wednesday, July 28—First Day.

Treatment of the Gravest Forms of Puerperal Sepsis.—Dr. Thomas Wilson of Birmingham introduced this discussion. He said that since the days of Semmelweiss the theory of puerperal fever had been placed upon a sound basis, with the result that the disease had been practically abolished in properly conducted lying-in institutions. In spite of this the mortality, and therefore probably the morbidity, from this affection had remained undiminished. The cases were scattered, and only here and there provision was beginning to be made for collecting them in hospitals or other institutions suitable for research and effectual treatment. As a consequence, the best treatment remained in many directions undetermined. It was now universally agreed that puerperal fever was due to infection of wounds and raw surfaces arising in parturition, the most common points of entry of the germs being at the placental site and through lacerations of the cervix and vagina. Many different germs had been proved to be exciting causes of the disease. Grave cases of puerperal fever might be defined as those which endangered the life of the patient, and as in the worst cases the *Streptococcus pyogenes* was the organism most frequently found, the discussion would chiefly be limited to this infection, which varied in gravity from slight and passing local inflammations to the most severe and rapidly fatal blood poisoning; in individual cases rapid and unexpected changes, either for better or worse, frequently occurred. The indications for treatment were (1) to attempt to limit the entry and spread of the infecting organisms, and (2) to support the patient. The most important point was that immediate and effective treatment should be undertaken without the least delay on the appearance of the first indication of infection, which was usually a rise in temperature, most frequently occurring on the second or third day after delivery. When the temperature exceeded 102 deg. F. a careful examination of the patient should be made, and this would include an examination of the lochia, and, if possible, a digital exploration of the uterus. Opinions differed as to the relative value of digital evacuation as compared with curetting, and of copious intrauterine douching as opposed to swabbing with strong antiseptics. The advocates of douching and strong antiseptics also disagreed as to the best drug to employ. Observers were more in accord on the necessity for rest, for a suitable nourishing diet, and for attention to the excretory functions. The places of alcohol and quinine in the treatment were still unsettled. Injections of antistreptococcus serum had generally proved disappointing, and treatment by vaccines was still too recent, and had been employed in too few cases for the formation of a valid opinion. There was general agreement that pus should be let out at the earliest possible moment by the nearest route. In peritonitis incisions and drainage through the posterior vaginal vault and abdominal wall had been employed with no very satisfactory result. Abdominal or more frequently vaginal hysterectomy had been employed with a fair amount of success in certain conditions, such as infected fibroids or infected rupture of the uterus, but in ordinary cases of puerperal infection these operations had generally proved disappointing. Where the infection had spread along the veins, giving rise to phlebitis with no obvious secondary deposits, the veins had been ligatured or removed through the peritoneal cavity or by a subperitoneal operation. Diagnosis of these cases was difficult, and the indication for operation uncertain, and hitherto the number of recorded successful cases was small. Patients who were gravely septic bore anesthetics and operations very badly, and, on the other hand, recovery often took place without the aid of surgery in cases that appeared practically hopeless.

Professor Yehling of Strasbourg said that the chief thing wanted was better diagnosis: at present, we could only diagnose a bad case when it was too late; it was impossible to say if the streptococci were hemolytic or nonhemolytic, and it was possible that one form could change to the other. We had never clearly separated sapiemia from septicemia. Coli bacillus injection was sometimes bad. As regarded treatment, he considered serum useless and he had never seen a good result from that; vaccine therapy might prove the better, but our experience of it was too short. He advocated a vaccine prepared from the patient herself, and had tried prophylactic vaccine treatment before parturition. He did not agree with S. Wilson about local investigation, and would not examine the interior of the uterus in the first week. He had had good results from douching when injection was saprophytic, or by the *Bacillus coli;* but it was no use in septicemia, and in that condition besetting real dangerous. The prognosis in thrombotic septicemia was uncertain; he had known recovery follow when 50 rigors had occurred.

Professor Murdoch Cameron of Glasgow said he swabbed out the uterus with camphor and carbolic acid equal parts, and never used the curette.

Dr. Munro Kerr of Glasgow thought that the reason why the results in hospitals were better than in private practice was because in the former more care was given to disinfecting the bulva. He thought early exploration of the uterus was undesirable in the slighter forms, and would not do it unless there was reason to think that some placenta or membranes had been left. He was opposed to curetting. He agreed with Professor Fehling that the distinction between the graver and the lighter forms could not be made by bacteriological examination, and we must depend on clinical evidence. He thought that the appearance of early

symptoms of peritonitis always indicated a fatal issue. He disapproved of serum, but thought that vaccines might be useful in chronic cases.

Dr. Hastings Tweedy of Dublin, Master of Rotunda Hospital, did not agree with Dr. Wilson that sepsis had been abolished in lying-in hospitals, and thought that we must pay more attention to the morbidity than the mortality rate. He pleaded for more extensive use of the posterior vaginal incision with gauze drainage; it was a very simple operation, and could be done on the bed. General anesthesia was very badly borne in these cases. He did not agree with Tebling about waiting a week before exploring the uterus. He used gloves. He attached importance to anteflexion or retroflexion as a cause of sepsis by damming up secretions.

Dr. Henry Jellett of Dublin thought that a localized abscess in Douglass's pouch was generally associated with *Bacillus coli* infection from the rectum. He asked what were the indications for opening the posterior fornix. Prior, to whom the operation was due, performed it in every case of sepsis. He himself would confine it to cases in which there was a swelling; he made a large opening, and washed out with hydrogen peroxide, and plugged tightly with iodoform gauze. He used a blunt curette.

Dr. Fred Edge of Wolverhampton drew attention to the danger of introducing infection from vulva and vagina into the uterus in examining slight cases of sepsis unless care were taken to disinfect the vulva and vagina. He used the finger and the blunt curette, and washed out with saline solution.

Dr. Alfred Smith of Dublin said that he opened the abdomen, put a glass tube in each angle of the wound, and applied continuous irrigation in cases of peritonitis. He thought that the diagnosis of thrombotic septicemia was extremely difficult. He placed reliance on the leucocyte count and thought that when it was low it was a favorable case for operation.

Dr. Cuthbert Lockyer of London said that he treated severe cases by first making a thorough exploration with the gloved hand, at the same time taking a swab for bacteriological examination. He had given up curetting entirely, but swabbed the ulcers out with iodine, and left in a gauze drain. If the bacteriologist reported a streptococcus infection, he gave at once an injection of 30 c.c. polyvalent serum, whilst a vaccine was being prepared, the latter requiring about 48 hours. He had lately given more frequent doses of vaccine, repeating the injection during the positive phase.

Dr. Purslow of Birmingham alluded to the difficulty of finding hospital accommodation for these cases, and thought that the municipality should admit them to the contagious disease hospital, as was already done in some places.

Dr. Wilson in closing said that he had mentioned the temperature as a guide between slight and severe cases, as it was the most convenient means of deciding. He would explore the uterus in all cases in which benefit had not followed intrauterine irrigation after waiting twelve hours.

Midwifery in Private Practice: A Criticism of Method Based on Actual Results.—Dr. J. J. Austin of Belfast read this paper, which was based on 465 consecutive cases. Among these were: 29 abortions, 9 breech presentations, 1 accidental hemorrhage, 1 eclampsia, and 5 adherent placenta. There were no maternal deaths. Forceps were used in 1.3 per cent. of multiparæ, 26 per cent. of primaparæ, and 8.7 per cent. of all cases in the second half of the series he wore gloves. He thought that vaginal examination was indispensable in private practice. He used the douche in all cases at the conclusion of the labor.

The Treatment of Uterine Cancer in the Later Months of Pregnancy.—Dr. Lockyer of London read this paper, which was based on a study of two cases. In the first he performed conservative Cesarean section, the disease being too far advanced for radical treatment; the child survived, the mother recovered from the operation, but died five weeks later from exhaustion. The second case he performed Cesarean section followed by Wertheim's panhysterectomy, and this was the treatment he advised whenever it was possible.

(*To be continued.*)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting Held April 26, 1909.

Dr. H. Seymour Houghton in the Chair.

The Dispensary Evil.—Dr. Arnold Sturmdorf said that the dispensary evil had assumed such proportions as to make it necessary to do something toward its abatement, and there were two phases of the question, one the effects upon a certain class of physicians, especially the younger members of the profession; two, the effects upon the patients. There was charity both to the one who received and to the one who gave. He asked that a committee be appointed by the president to take some active steps in this matter.

Dr. Wolff Freudenthal moved that the president appoint a committee of three, to be sent as delegates to the Eastern Medical Society, who had already taken up this matter, to take into consideration what could be done in abating the dispensary evil. This was seconded and carried.

The scientific session was devoted to a symposium on military medicine.

The Military Obligations of the Medical Profession.—Lieutenant-Colonel Jefferson R. Kean, U. S. A., of Washington, D. C., read this paper. (See page 253.)

Some Features of the Medical Department of the Navy in Peace and in War.—Surgeon Charles F. Stokes, U. S. N., of Washington, D. C., read this paper. (See page 256.)

The National Guard Surgeon.—Lieutenant-Colonel Wm. G. Le Boutillier, Div. N. G. N. Y., read this paper. (See page 259.)

Hygiene of the Regiment.—Captain Harlow Brooks, Seventh Regiment, Inf., N. G. N. Y., read this paper. (See page 261.)

Instruction of the Hospital Corps.—Sergeant First Class Edmund Prince Fowler, Seventh Regiment, Inf., N. G. N. Y., read this paper. (See page 262.)

Major William S. Terriberry, Field Hospital, N. G. N. Y., said that it was necessary in military medicine, as in civilian medicine, to specialize in order to obtain the best results. That for the past two or three years he had been paying some attention to one particular point in the machinery of the medical department, *i.e.* to create a field hospital in the State service, which was an organization for this one purpose—the relief of the sick and wounded at the front. The medical service in the field was divided into two portions: (1) The service of the front, which was performed by all parts of the medical department that marched with the troops; (2) the service of the rear, which was performed by all parts of the medical department which stayed behind the army at its base or on its lines of communication. On the march the relief of the sick and wounded was carried out as follows: Sick, wounded, or footsore men who could not keep up with the column fell out and were attended to by the regimental detachments of the medical department. After being attended to they were left by the roadside, if seriously sick or injured, accompanied

by a hospital corps man. At the rear of the division, which was about eleven miles long when in column, marched the field hospitals. When they came up to the sick or injured that had been left, they gathered them up, placed them in their ambulances, and treated and cared for them until they could be sent back to the rear. As the army advanced the line of communication lengthened, and along this line came supplies of ammunition, food, and forage carried in wagons, railroad trains, and boats. When these vehicles were emptied they returned with the sick that the field hospital had collected and transported them to the base. In actual battle the regiments were deployed into line and these lines were apt to be very long. In the rear of these deployed regiments the medical department established dressing stations under cover, but close to the line. The wounded were brought back to these dressing stations and treated. The field hospitals, of which there was one to three regiments, established themselves out of range of artillery fire, in a position centering upon the regimental dressing stations. The field hospitals then sent out a detachment advanced to a point as close to the regimental dressing stations as it was safe to bring ambulances. This station, known as the ambulance station, received wounded from the dressing stations and transported them by ambulance to the main position of the field hospital. There they were treated, emergency operations were performed, and the patients were turned over to the service of the rear and sent back to the base. The service in base hospitals was similar to the service in civilian hospitals. If the patient in the base hospital recovered quickly, he was sent to a convalescent camp to gain strength and from thence he was returned to his regiment at the front. If, on the other hand, he required long-continued treatment, he was sent to a general hospital established in the home territory, and if no longer of military use was discharged. When troops in battle were intrenched, regimental dressing stations in the trenches were of great importance. The wounded remained in the trenches as the safest place and were removed under cover of darkness to the field hospital. When the approaches from the rear to the trenches were safely under cover, men might be moved back at once. The medical service of the front was a very complicated matter, requiring special training in the use and care of transportation, and in the methods of the different arms of the line and of other staff departments. The general medical profession, untrained in military affairs, would be of little use at this point, but of great use in the service of the rear. As American citizens it is the duty of the medical profession to create public sentiment for a large medical department in the army, in order that a sufficient number of men might be trained to perform the complicated duties of the service of the front.

Major Theron W. Kilmer, Twenty-second Regiment, Corps of Engineers, N. G. N. Y., said that not only the numerical value, but the hygienic value of the men should be considered; not how many men had they, but how good are they. During the last few years there had been a great metamorphosis accomplished in the N. G. N. Y. Surgeons had been appointed who were attending to their duties at all times. To-day in sanitary matters the regimental surgeon's word was law; he had to be obeyed. The men belonging to the N. G. N. Y. to-day were fit for their jobs.

Captain Joseph Siler, U. S. A., Governor's Island, said that in 1900 the Secretary of War appointed a commission of officers of the army to investigate tropical diseases in Cuba, among them being Drs. Reed, Carroll, Agrimonte, and Lazear. They demonstrated that yellow fever was transmitted by the mosquito, and Dr. Carroll himself was the first to subject himself to the bite of this insect for experimental purposes. He, as the result of this, developed a severe attack of yellow fever, which left him with an invalidated heart. In 1907 Dr. Carroll died as the result of this heart condition. Only recently it had been learned that his family were not in good financial condition; he left a mother, a widow, and several children. Last year, through the efforts of the Medical Society of the County of New York and other societies, Congress gave the widow a monthly pension of $125. Just before his death Dr. Carroll bought a house in Washington costing about $7,000 and the medical officers themselves had raised $3,000, and he asked that any member present who wished to help pay off the indebtedness on that house would do so, even though the sum be a small one.

Lieutenant Reginald H. Sayre, Ordnance Officer, Squadron A, Cavalry, N. G. N. Y., said that the number of medical officers in the army was too small. In 1898 he had written the Surgeon-General in behalf of a friend of his who wished to go to the front, and was informed in reply that there was no room, that all the positions were filled, and that he had more applications than he knew what to do with. They all knew there was ample room for qualified medical men. During the past fifteen years there had been a wonderful change in the medical department organization of the N. G. N. Y., although most of the hospital corps needed more men to do effective work.

THE AMERICAN THERAPEUTIC SOCIETY.

Tenth Annual Meeting, Held at New Haven, Conn., May 6, 7, and 8, 1909.

F. H. Gerrish, M.D., of Portland, Me., President, in the Chair.

(*Concluded from page 252.*)

Saturday, May 8—Third Day.

The Dietetics of Chronic Diseases.—Dr. William H. Porter of New York read this paper. The conclusions at which he arrived from his study of the subject were as follows: That all foods were divisible, primarily, into two distinct classes, the purely vegetable and the purely animal; that both were divisible into five distinct groups of substances; that neither class was absolutely perfect in composition; that the animal approached the more nearly to perfection; that the animal was more easily digested and assimilated; that the animal was more economic; that to secure a perfect or ideal diet the two classes must be used together; that between the two extremes we had two other dietaries, one in which the two classes were blended perfectly, and one in which the two were less perfectly adjusted; that the latter was often spoken of as a purely vegetable diet, while in reality it was a poor form of mixed diet—hence there was much confusion in the minds of many who discussed the subject; that when an ideal diet was secured, one which just suited the individual case, marvelous results could be obtained, especially when it was used in conjunction with well directed therapeutics.

Hypodermatic Medication in Modern Therapy.—Dr. Spencer L. Dawes of Albany, N. Y., made an urgent plea for the more general adoption of this method, on account of its distinct advantages over others. He also advocated intramuscular injections, instead of subcutaneous, stating that for several years it had been his practice to employ these in every instance where the hypodermatic syringe was used, especially on account of the more rapid absorption thus secured. If in the use of the hypodermatic method, abscess, erythema, induration, or any other local disturbance occurred, he believed that almost without excep-

tion it was due either to want of care or knowledge in selection of site and mode of operation, or to unsterile instruments or unsterile or improperly prepared or preserved solutions.

Dr. J. Blake White of New York said he would take some little exception to Dr. Dawes' advice to employ only nonirritating remedies hypodermatically. Personally he had used some which were irritating with the most satisfactory results. Thus, he had found that sciatica was promptly relieved by the injection of tincture of iodine combined with atropine. He had also frequently injected the same combination directly into the lung, with no harmful effects. He was accustomed to use a double-barreled syringe, which he had himself devised; one barrel being for the solution employed and the other for air. With this, asepsis could be readily insured, and he had made as many as two hundred injections in a single case without the occurrence of abscess.

Dr. J. F. Fotheringham of Toronto referred to the enormous advantage of the hypodermatic method in acute diseases, like pneumonia. It might be that after the attack had lasted four or five days the patient's stomach would give out entirely. Here the use of the required remedies hypodermatically assured their action on the system; a result which could not be attained in any other way. As to technique, for a long time now he had given up injecting anything but sera into the subcutaneous tissue. The more slant there was to the needle, the greater the danger of striking a nerve; while if we put the needle in straight we entered an anesthetic area.

Dr. William H. Porter said that at a certain hospital in New York it was at one time found that in almost every case in which the nurses used the syringe an abscess resulted. They employed subcutaneous injections, and there were about thirty abscesses. On the other hand, not a single abscess followed the injections made by the house staff, who employed the intramuscular method.

Dr. Dawes, in reply to Dr. White, said he had purposely stated that as a rule drugs which were irritating, as well as those which were not readily soluble and those which were bulky, should be avoided. Of course, there might be exceptions.

The Effects of Modern Synthetics.—Dr. F. P. Morgan of Washington, D. C., having briefly reviewed the history of synthetic chemistry, stated that the most important step in this history, so far as its relation to medicine was concerned, was the recognition of the fact that an alteration in the chemical composition of organic compounds, no matter how slight in character, might effect a material change in their pharmacological properties. Several illustrations were cited showing that a definite relationship exists between chemical composition and pharmacological action. The recognition of this truth had been very largely instrumental in the production of a great mass of modern synthetics; exerting a beneficial influence upon the development of medical science, particularly along the line of experimental pharmacology. The paper included the data obtained as the result of a recent investigation conducted by the U. S. Department of Agriculture with regard to the harmful effects of acetanilide, antipyrine, and acetphenetidin. The object of the inquiry was not to depreciate in any way the value of these medicinal agents, but rather to furnish information to the public which would enable them to understand that the drugs should be employed with caution, in the absence of reliable medical advice. A table was given showing that 814 cases of poisoning, with 28 deaths and 138 instances of habitual use, were reported by 400 physicians to whom inquiries had been sent, and in conclusion the speaker asked how many such cases could be collected from the 125,000 physicians scattered throughout this country.

Alcohol Injections in Neuralgias, Especially in Tic Douloureux.—Dr. O. G. T. Kiliani of New York read this paper (see Vol. 75, p. 957).

Superficial Dermatitis of the External Auditory Canal.—Dr. Clarence J. Blake of Boston said that the peculiarity of its structure and its function, as well as its relationship to an important organ of special sense, made deviations from the normal in the skin lining the external auditory canal a matter of more importance than would otherwise be the case. The primary mechanism in the affection named was a dermal hyperemia, with serous transudation and elevation of the thin epidermal layer, which, under maceration, disintegrated, and, mixing with the serum, afforded an outflow microscopically simulative of pus. The treatment consisted of thorough cleansing and drying, repeated until the exfoliated epidermis had been completely removed, and when this had been effected the denuded surface should be painted with a strong solution of silver nitrate. The frequently accompanying epidermal exfoliation of the outer portion of the canal should be cleansed with a weak peroxide and sodium bicarbonate solution, followed by the application of alboline, while the intense itching often accompanying this condition might be relieved by the application of a vaseline ointment containing tincture of benzoin and sodium salicylate. In the chronic forms of epidermal disturbance the epidermal layer seemed to have lost its normal progression, or to have had it so much impaired as to result in the accumulation of superimposed epidermal layers *in situ*. In some instances there was formed a mass of epidermis, in more or less well defined strata, nearly or wholly filling the inner half of the auditory canal, the keratosis obturans of Wreden.

Subphrenic Abscess.—This paper, by Dr. Carl Beck of New York, was read in abstract by Dr. H. E. Gallant. Since the beginning of the year 1892 Dr. Beck had met with fifty-five cases, of which thirty-eight recovered; giving a mortality of a little less than thirty-one per cent. Fourteen were of appendicular origin, and the remainder from a considerable variety of sources. There was only one treatment of the condition, namely, free opening, as a rule, after resection of one or more of the ribs.

Medical and Surgical Treatment of Senile Enlarged Prostate.—Dr. Oliver C. Smith of Hartford, Conn., said that in the treatment of the hypertrophical prostate cases must be individualized, and each one managed according to its peculiarities. We might, however, in a broad way classify our cases and determine which should be treated medically and hygienically, which should be placed upon habitual use of the catheter, which were the proper cases for operation, and, if operation was required, whether it should be a palliative one for drainage and rest of the bladder, or whether, if prostatectomy was decided upon, the suprapubic or perineal route should be selected. The treatment in the various conditions was detailed and the advantages of the different operations discussed. Since June, 1902, Dr. Smith had operated on sixty-eight cases, of which fifty-one were benign and thirteen malignant. Perineal prostatectomy was performed upon fifty-one cases of benign disease, and the total mortality in benign cases, patients dying within two weeks, was twenty per cent. Of these, six died of conditions not chargeable to the condition of the bladder or effects of the operation, one died of pulmonary embolism, after operation, and three died as the result of bladder conditions which operation could not relieve; leaving an immediate mortality of eight per cent. Fifty-nine per cent. are living to-day, without prostatic or serious urinary symptoms, at periods varying from a few months to seven years after the operation. Thirteen per cent. more lived for some time, and died of causes unconnected with the genito-

urinary system. The first fifty operations were performed with the aid of a retractor. The last fifteen have been done without the tractor, in some instances pressure having been made from above, over the bladder, to bring the prostate within reach.

The Therapeutics of Some Obstetric Conditions.—Dr. B. A. CHENEY read this paper. For the prevention of eclampsia, he said, more attention to the expectant mother than is usual in general practice was demanded. To prevent further convulsions when these had already begun chloroform was unexcelled by any drug, and hydrated chloral, which could be given per rectum, was a valuable adjuvant. Next veratrum should be given hypodermatically, and repeated every hour till the pulse was soft and less than seventy. For the elimination of absorbed toxins hot enemata of salines or even croton oil might be employed, as well as colon infusion of salt solution and the application of hot packs to the whole body. In a few cases characterized by a pulse of high tension and fullness, venesection had been effective. The most important indication was to empty the uterus.

Therapeutic Drainage in Cases of Uterine Obstruction.—Dr. A. ERNEST GALLANT of New York advocated the following plan: (1) Whenever the uterosacral ligaments showed evidences of previous inflammation, the bands, or thickening, were gradually stretched by massage, and every third day the vagina was tamponed, after the vault had been painted with pure ichthyol. (2) When the internal os was found tender to the passage of the sound or the flexion was 90° or more, under anesthesia the adhesions were forcibly stretched, the cervix dilated, preferably by graduated sounds, and the mucous membrane curetted; after which irrigation with hot 1 to 2,000 potassium permanganate solution was practised. (3) The bivalve drain was then introduced and in some instances sutured in place with silk worm gut, to remain for some months; a very necessary feature if permanent drainage and restoration of the cervix to its normal shape and caliber were desired. (4) A roll of gauze was inserted in the vagina, its upper end being placed directly under the cervix, in order to serve the double purpose of a wick drain and uterine support. (5) After tenderness and the discharge had subsided, a pessary of suitable size and shape was inserted and worn until the fourth month of pregnancy or permanently, as the case might require. (6) Trachelorrhaphy was practised in a few instances of deep laceration into the fornices, and where the cervix was greatly hypertrophied and cystic.

Recent Investigations as Related to the Therapeutics of Cardiac Arrhythmias.—Dr. THOMAS E. SATTERTHWAITE of New York read this paper (see page 833).

Treatment of Stokes-Adams Syndrome.—Dr. REYNOLD WEBB WILCOX of New York read this paper. The syndrome was characterized by bradycardia, cerebral attacks, and pulsation of cervical veins in excess of pulse rate. The treatment was prophylactic, mechanical, and medicinal. As regards the last named, a combination of atropine and strychnine had usually been advocated. Atropine, however, was useless in affections of the myocardium, of which the syndrome was the expression. Alcohol had at times apparently shortened the attacks. In those instances in which the speaker had employed cactus, recovery from the attacks had taken place. If the symptoms were very urgent it should be preceded by ammonia, hypodermatically. After the acute attack it was well to give arsenic iodide for a considerable period. If a syphilitic history was obtainable the prognosis was much more favorable, and vigorous antisyphilitic treatment should be instituted.

Acapnia as a Factor in Disturbances of Function, and the Prevention of Acapnia.—Dr. YANDELL HENDERSON, said that Haldane's investigations had demonstrated a new constant of health, namely, the pressure of carbon dioxide in the arterial blood; so that for the regular performance of the various functions it was essential that this should be maintained uniformly. This was the object of the respiration. The name acapnia had been given to diminution in carbon dioxide, and this could be produced by excessive respiration. Acapnia he believed to be the cause of surgical shock, though this hypothesis had not as yet been proven. In support of it we had the well-known fact that pain of any sort causes excessive respiration. When extreme pain ceased the respiration also stopped. In animals or men under operation it sometimes happened that the respiration became excessive. It was therefore important that the initial stage of anesthesia should be as brief as possible, and the preliminary use of nitrous oxide gas was thus of service in preventing acapnia. Ether itself, it was to be remembered, was a respiratory stimulant. It was just as important to bring the patient out of anesthesia without excessive respiration as to get him into it without this. Another phase of the matter: The congestion which developed when in a laparotomy the abdominal viscera were wholly exposed to the air had hitherto been unexplained. The speaker said he had data to show that the rate at which carbon dioxide exhaled from such exposed organs was forty times as great as that of the exhalation from the skin. Therefore, this was one of the causes of acapnia, and it could easily be avoided by protecting the viscera by means of some impervious covering.

Pain; Its Diagnostic and Therapeutic Value.—Dr. EDWARD D. FISHER of New York said that the distribution, localization, and character of pain were diagnostic points of the greatest value. If it were extremely intense, however, it became itself the main factor to be considered, and had little significance either as a diagnostic or a protective factor. The pain in neuralgia was shooting and severe, while that of neuritis was less severe and burning in character. Pain in an organ itself was generally dull, while that of the capsule was sharp and severe. This was illustrated in the case of the brain and its meninges. If the pain was stretching in type and widely distributed, as in tabes, it pointed to an affection of the peripheral sensory nerves; but if it was permanently seated, like the girdle pain of tabes, it was probably due to the meningitis. Having given a number of other illustrations, he said that localization of pain in tumors of the brain was rarely an aid in the localization of the tumor except when the meninges were involved. Pain was protective in so far as it enabled the individual to avoid danger. It was also valuable by causing the individual to rest. Often this was all that was necessary to prevent serious disease of the part or organ affected. This was strikingly seen in pleurisy as well as in appendicitis and intestinal affections in general. In fact, inflammatory conditions everywhere called for cessation of movement. Nature compelled rest by the excessive pain, and thus allowed an opportunity for the leucocytes to carry off the infectious materials, or for the sera or antitoxins to resist the destructive process.

Officers Elected.—The following officers were elected: *President*, Dr. James C. Wilson of Philadelphia; *First Vice-President*, Dr. A. D. Blackader of Montreal; *Second Vice-President*, Dr. Howard Van Rensselaer of Albany, N. Y.; *Third Vice-President*, Dr. Robert T. Morris of New York; *Secretary*, Dr. N. P. Barnes of Washington, D. C.; *Treasurer*, Dr. A. Ernest Gallant of New York; *Members of the Council*, Drs. T. E. Satterthwaite of New York, F. H. Gerrish of Portland, Me., J. Blake White of New York, and C. J. Blake of Boston; *Members of the Standing Committee on Therapeutic Research*, Drs. S. L. Dawes of Albany, N. Y., and H. W. Wiley, of Washington, D. C. The next annual meeting of the Society will be held in Washington in May, 1910.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

California State Board of Medical Examiners.

San Francisco, April 6, 7, and 8, 1909.

ANATOMY.

1. Give topography of the bronchi on the ventral and dorsal surfaces of the body. (Diagram.)
2. Give course of the adult duodenum and position of the pancreas with reference to the ventral aspect of the vertebral column. (Diagram.)
3. What articulations have an interarticular fibrocartilage?
4. What is the arrangement of the lumbar fascia?
5. Give brief outline of the arrangement and plan of distribution of the sympathetic nervous system.
6. Name the various bony prominences or landmarks which can be easily felt and recognized in the head and face, which afford the means of mapping out the important structures comprised in this region.
7. What are the veins of the neck which return the blood from the head and face?
8. What nerves innervate the tongue?
9. Give location of the thoracic duct and indicate what portions of the body are drained by it.
10. What arteries supply the rectum, and of what arteries are they branches?

HISTOLOGY.

1. Explain the difference in the histological structure of veins and arteries.
2. Describe the histological structure of the tonsils.
3. Give the histological structure of red and yellow bone marrow.
4. Describe the development of bone.
5. Draw a diagram of a cross section of an ovary showing one ripe Graafian follicle.
6. Describe the histological structure of the skin.
7. Describe the histological structure of the pancreas.
8. Identify two specimens.
9. Identify two specimens.
10. Identify two specimens.

PHYSIOLOGY.

1. Define and give illustrations of: (*a*) Autolysis. (*b*) Plasmolysis.
2. Give the probable location of the chief motor areas of the cerebral cortex.
3. Describe the distribution and function of the spinal-accessory nerve.
4. (*a*) Where are the trophic centers of the skeletal muscles? (*b*) Where is the parturition center?
5. Describe the blindness ensuing from a destructive lesion of the right optic tract.
6. Describe the innervation of the respiratory movements.
7. Explain the movements of the large intestine.
8. (*a*) What is the function of the portal system of veins? (*b*) Mention the principal branches. (*c*) How do they differ from other veins?
9. Why are the arteries in a state of emptiness after death?
10. Define: (*a*) Atelectasis. (*b*) Alexins. (*c*) Protozoa. (*d*) Ptyalin. (*e*) Caul (*f*) Chemotropism. (*g*) Colostrum. (*h*) Catamenia. (*i*) Eupnea. (*j*) Strabismus.

CHEMISTRY AND TOXICOLOGY.

1. (*a*) What is the definite ratio of increase or difference in the methane or marsh gas series? (*b*) What is an alcohol? (*c*) How are organic acids produced?
2. Select the five most important reagents for an urine analysis outfit and state why you selected each.
3. (*a*) What body waste does excess of urea signify? (*b*) What is the normal amount excreted in twenty-four hours? (*c*) What will increase its quantity? (*d*) What should be taken into account in establishing its amount in relation to the individual?
4. (*a*) Describe Ehrlich's Diazo-reaction. (*b*) Of what diagnostic importance is it?
5. (*a*) What acids produced from carbohydrates by bacterial action in the intestine? (*b*) Do these acids stop the action of the pancreatic juice? (*c*) What putrefactive products in the intestine from bacterial action?
6. (*a*) In what form may indol be found in urine? (*b*) Outline analysis. (*c*) What is its clinical significance?
7. Give action, where formed, products and classes of foods digested by: (*a*) Trypsin. (*b*) Amylopsin. (*c*) Steapsin.
8. (*a*) Why would you not give the alkaline carbonate as antidote in oxalic acid poisoning? (*b*) Describe symptoms and outline treatment for a case of carbolic acid poisoning.
9. (*a*) Give the symptoms of poisoning from mushrooms. (*b*) What difference would you note in the stains on the skin between nitric acid and sulphuric acid poisoning?
10. Symptoms: Dryness of the throat, metallic taste, great thirst, colic (relieved by pressure), abdominal muscles rigid, constipation, cramps in legs, paralysis of the extremities, convulsions, blue line at margin of gums. Name the poison.

GENERAL DIAGNOSIS.

1. Describe the anemias.
2. Describe duodenal ulcer.
3. Describe acute poliomyelitis anterior.
4. Differentiate conjunctivitis and iritis.
5. Describe abdominal pains in the male and give significance of each.
6. Differentiate renal and hepatic colic.
7. Differentiate aortic and mitral valvular diseases.
8. Describe Raynaud's disease.
9. What are the causes of endocarditis?
10. Give early symptoms of gastric ulcer.

PATHOLOGY.

1. Discuss the etiology of thrombosis.
2. What is the microscopic appearance of the liver in hypertrophic cirrhosis?
3. In normal feces, what is the percentage of bacteria (dry, by weight)? How does it vary in constipation, diarrhea?
4. Name the diseases, the diagnosis of which may be made entirely by blood smears, blood culture, blood count, and serum reaction.
5. What is the microscopic character of the blood in Banti's disease? What are the gross post-mortem findings?
6. Describe the mechanism of jaundice due to obstruction of the extrahepatic bile ducts.
7. Secondary to tonsillar infections, what diseases or pathologic lesions may result?
8. In what different ways may arteriosclerosis cause death?
9 and 10. The diagnosis of pathologic specimens under the microscope.

BACTERIOLOGY.

1. (*a*) Differentiate endogenous and exogenous infections. (*b*) Name one organism associated with each condition.
2. (*a*) Name the organism of chancre. (*b*) Give morphology and staining peculiarities. (*c*) Name the organism of chancroid.
3. (*a*) Name two methods of animal inoculation. (*b*) State the precautions necessary to satisfactory results.
4. (*a*) State how to prepare potato for cultural purposes. (*b*) Name two organisms to whose growth it is suitable.
5. (*a*) Name three pyogenic organisms. (*b*) Three toxine producers. (*c*) Five pathogenic organisms positive to Gram's method.
6. Name the most frequent causal organism in: (*a*) Appendicitis. (*b*) Acute cystitis.
7. (*a*) Name three anaërobic bacteria. (*b*) Describe a method of cultivating anaërobins.
8. Define: (*a*) Leucomain. (*b*) Pleomorphous. (*c*) Agglutin. (*d*) Alexin. (*e*) Phlogistic.
9. Examination of two slides.
10. Examination of two slides.

OBSTETRICS.

1. Describe a four months' fetus sufficiently exact to be of value as evidence in a medicolegal investigation.
2. State fully the reasons or conditions that make a fourteen to eighteen week abortion so very dangerous and describe the management of such a case.
3. What clinical symptoms occurring during labor would cause you to fear postpartum hemorrhage, and state in full what measures you would use to prevent its occurrence.
4. In a case of delayed second stage of labor, how long a time would you allow to elapse before interfering; and if interference were necessary what would you consider the indications for each different measure or method of terminating labor?
5. During pregnancy what clinical symptoms would be most likely to cause the patient to consult you for threatening toxemia of pregnancy? How would you verify the diagnosis and how would you manage such a case?
6. What do you consider the probability of frights, acci-

dents, etc., in a pregnant woman as a cause of birthmarks, monsters, etc.? What do you consider the most common cause of these abnormal cases and at what stage of fetal life are these abnormal conditions most likely to begin to develop, and what is the best means to prevent their occurrence?

7. In cases of breech or foot presentations, state fully why the dangers are greater to the mother and to the child, and how would you conduct such cases in order to minimize the dangers to both as much as possible?

8. Describe the symptoms occurring during the first stage of labor that would cause you to fear impending laceration of the cervix and what means would you use to prevent it?

9. Describe some of the conditions in a puerperal case that would lead you to use extraordinary precautions to prevent infection. In such a case state what directions or orders you would give to ignorant, unskilled help, and what you would do yourself to prevent its occurrence, and should it appear how would you manage the case under these conditions?

10. If you were to conduct an ordinary case of labor in the country among poor people, state fully what directions you would give to an ignorant, unskilled woman, acting as nurse, for the care of your patient for the first forty-eight hours after labor.

GYNECOLOGY.

1. Give location, shape, position and size of a normal uterus.

2. Name and give the attachments of the ligaments that hold the uterus in position.

3. Give the course of the ureters through the true pelvis, particularly their relation to the uterus.

4. Differentiate between Anteversion and Anteflexion of the uterus.

5. Describe briefly the following conditions: (*a*) Vicarious menstruation and places it may appear. (*b*) Supplementary menstruation. (*c*) Suppressed menstruation. (*d*) Emansio mensium (a form of Amenorrhea) with two causes.

6. Give tissues lacerated in incomplete laceration of the perineum. Same in complete laceration.

7. Give differential diagnosis between prolapsus of the urethra and urethrocele.

8. Differentiate between pelvic hematocele and hematometra.

9. Name the various kinds of cysts found in the pelvis, both from their origin and character of their contents.

10. Name the five different places at which a pelvic abscess may "point."

HYGIENE.

1. Define certified milk; inspected milk; Pasteurized milk.

2. How is a sand filter for water constructed, and what attention must be given to such a filter?

3. Describe the three large groups into which the different forms of food poison may be divided.

4. Discuss the economic loss to the public through insects that carry disease.

5. Name six (6) efficient disinfectants and indicate their application to different purposes.

6. What evidence is there that tuberculosis is a septicemia.

7. Enumerate an efficient and complete plan for the control of tuberculosis.

8. Why is an early diagnosis of syphilis important and what are the methods by which a positive diagnosis can be made?

9. What are the causes of the ordinary "colds" and what can be done to prevent them?

10. What progress has been made with the serum treatment of disease?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

CALIFORNIA STATE BOARD OF MEDICAL EXAMINERS.

San Francisco, April 6, 7, and 8, 1909.

ANATOMY.

3. The *articulations which have an interarticular fibrocartilage* are: The temporomandibular, sternoclavicular, acromioclavicular, wrist, and knee joints.

4. The *lumbar fascia* is arranged in three layers, with two enclosed spaces. The posterior layer is continued above as the vertebral aponeurosis, and below it is attached to the crest of the ilium; the middle layer is attached above to the last rib, and below to the crest of the ilium; the anterior layer forms the external arcuate ligament of the diaphragm above, and extends from the tip of the last rib to the first or second lumbar vertebra, while below it is attached to the crest of the ilium and to the iliolumbar ligament. The erector spinæ muscle is between the posterior and middle layers, and the quadratus lumborum between the middle and anterior layers. On the inner side each layer is attached to the vertebral column (lumbar or sacral vertebræ).

5. "The sympathetic nervous system consists of (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers." (Gray's *Anatomy.*)

6. The *bony landmarks in head and face* are: Nasion, glabella, inion, bregma, external angular process, zygomatic arch, temporal ridge, external auditory meatus, parietal eminence, mastoid process.

7. The external jugular, posterior external jugular, anterior jugular, internal jugular, and vertebral veins.

8. The *nerves which inervate the tongue* are: (1) The lingual branch of the inferior maxillary division of the trigeminus (sensation); (2) chorda tympani (taste); (3) lingual branch of the glossopharyngeal (taste and sensation); (4) hypoglossal (motor).

9. The *thoracic duct* extends from the second lumbar vertebra, where it commences by a dilatation, the *receptaculum chyli,* to junction of left internal jugular with left subclavian vein. The abdominal part is placed on the front of the body of the second lumbar vertebra, behind and to the right side of the aorta and on the inner side of the right crus; it then enters the thorax through aortic opening, on the right side of aorta, lying between it and the vena azygos major, and passes upward to right of aorta on right intercostal vessels. Opposite the fourth dorsal vertebra it passes to the left behind arch, and runs along the left side of the esophagus, behind the left common carotid artery. At the level of the seventh cervical vertebra it turns outward, and, passing behind left internal jugular and crossing first part of left subclavian artery, arches over the apex of the left pleura to open at the angle of union of the left internal jugular and left subclavian veins. (From *Aids to Anatomy.*)

The *portions of the body drained by it* are: Both lower limbs; abdomen, except upper surface of the liver; left half of thorax; left side of head and neck, and left upper extremity.

10. *Arteries which supply the rectum:* (1) Superior hemorrhoidal (from inferior mesenteric); (2) middle hemorrhoidal (from internal iliac), and (3) inferior hemorrhoidal (from internal pudic).

PHYSIOLOGY.

2. The *motor areas* are located and arranged on the cerebral cortex, immediately in front of the fissure of Rolando. At the upper part of the convolutions in front of this fissure are areas connected with the movements of the lower extremities; then from above downward are located the centers for movements of the shoulders, arms, wrists, fingers, face, lips, tongue, and larynx and pharynx.

3. The SPINAL ACCESSORY NERVE is *distributed* to the Sternomastoid and Trapezius muscles; some fibers are also supposed to pass to the larynx, pharynx, and heart. Its *function* is motor to the muscles just named; indirectly, phonation, and deglutition may be aided, and the heart may also be slightly inhibited by fibers from this nerve.

4. (*a*) The trophic centers of the skeletal muscles are situated along the whole extent of the spinal cord.

(*b*) The parturition center is in the first and second lumbar segment of the spinal cord.

5. In a destructive lesion of the right optic tract there will be blindness of the right halves of both retinæ; hence the left halves of the field of vision of both eyes will be lost, and only objects placed to the right of the median line will be seen.

8. (*a*) The *function of the portal system of veins* is to collect the venous blood from the viscera of digestion (stomach, intestine, and pancreas), and from the spleen, and to carry it to the liver, where the portal vein ramifies throughout the liver in the manner of an artery, and ends in capillaries, from which the blood is collected with the hepatic veins.

(*b*) Superior mesenteric, inferior mesenteric, gastric, and splenic.

(*c*) *The veins of the portal system differ from other veins,* in: (1) Beginning and also ending in capillaries; (2) having no valves; (3) being single.

10. (*a*) *Atelectasis* is the condition in which the air vesicles of the lungs are collapsed.

(*b*) *Alexins* are substances found in the blood which have antibacterial properties, and give immunity against certain toxins.

(*c*) *Protozoa* are the lowest form of animals, consisting of unicellular animal organisms.

(*d*) *Ptyalin* is a ferment found in the saliva, capable of converting starch into maltose and dextrose in an alkaline medium.

(*e*) *Caul* is a name given to the fetal membranes; also to the great omentum.

(*f*) *Chemotropism* is the destruction of bacteria by leucocytes, or *vice versa.*

(*g*) *Colostrum* is the first milk from the mammary glands after the birth of a child.

(*h*) *Catamenia.* The menstrual discharge.

(*i*) *Eupnea* is normal, easy breathing.

(*j*) *Strabismus* is a deviation of one of the eyes, so that both eyes do not look at a given object at the same time.

CHEMISTRY AND TOXICOLOGY.

1. (*a*) The definite ratio of increase or difference in the methane series in CH_2.

(*b*) An *alcohol* is the hydroxide of a hydrocarbon radicle, which is capable of reacting with an acid to produce an ester and water.

(*c*) The volatile, fatty, organic acids are produced from corresponding alcohols by the substitution of an atom of oxygen for H_2 in the CH_2OH group of the primary alcohol.

Thus:

CH_2OH	$COOH$
|	|
CH_3	CH_3
Ethyl alcohol.	Acetic acid.

2. *Five most important reagents for a urine analysis outfit:* (1) Acetic acid (to acidify the urine when necessary); (2) nitric acid (to test for albumin, also for bile); (3) Fehling's solution (to test for sugar); (4) sodium hypobromite solution (for quantitative test for urea), and (5) solutions for the diazo reaction for typhoid fever; these are sulphanilic acid in HCl, and sodium nitrite.

3. (*a*) Proteid material.

(*b*) About one ounce to an ounce and a half.

(*c*) The ingestion of large quantities of watery drinks.

(*d*) Age, sex, weight, diet, and disease.

4. For the diazo reaction of Ehrlich, two solutions are required: (1) A saturated solution of sulphanilic acid in a mixture of 50 c.c. of hydrochloric acid and 950 c.c. of water; and (2) a 0.5 per cent. solution of sodium nitrite.

To make the test, 1 c.c. of (2) is added to 40 c.c. of (1) and the mixture thoroughly shaken. Equal quantities of this mixture and the urine to be tested are shaken together in a test tube, and 1 c.c. of ammonia is then floated upon the surface, when, in an affirmative result, a red band is formed at the junction of the fluids.

Its diagnostic value is uncertain. Von Jaksch "disclaims for this test any clinical importance whatever." Others have claimed that the reaction is pathognomonic of typhoid; but it has been found in other diseases besides typhoid—namely, phthisis, pneumonia, measles, scarlet fever, smallpox, and malaria.

5. (*a*) *Acids formed* are: Acetic, lactic, butyric, succinic, paralactic, and biliary acids.

(*b*) No.

(*c*) Indol, skatol, ammonia, sulphuretted hydrogen.

6. (*a*) As indican (indoxyl potassium sulphate).

(*b*) *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chlorid, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

(*c*) *Indicanuria* is found in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc. (From Witthaus' *Essentials of Chemistry.*)

7. (*a*) *Trypsin* is formed in the pancreatic juice; it acts on proteids, turning them into proteoses and peptones, in an alkaline or neutral medium.

(*b*) *Amylopsin* is formed in the pancreatic juice; it acts on carbohydrates, turning them into dextrin and sugar.

(*c*) *Steapsin* is formed in the pancreatic juice; it acts on fats, emulsifying and saponifying them.

8. (*a*) The alkaline carbonates are not used in oxalic acid poisoning, because the oxalates which they would form are soluble, and are nearly as poisonous as oxalic acid.

(*b*) *Symptoms in carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperatures are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

Treatment: Emetics, white of egg, stimulants; sodium sulphate, or alcohol may be given as antidotes.

9. (*a*) *Symptoms in poisoning from mushrooms:* Sudden onset, great prostration, cold perspiration, headache, fever, rapid and feeble pulse, pain in abdomen, diarrhea, cyanosis, urine scanty or suppressed and albuminous or bloody; stupor and delirium.

(*b*) Stains on the skin, from *sulphuric acid,* are first whitish and then become brown or black; those from *nitric acid* are first yellow and then become a dirty brown.

10. The poison taken was lead.

4. GENERAL DIAGNOSIS.

CONJUNCTIVITIS.	IRITIS.
1. No change in iris.	1. Discolored and altered iris.
2. Pupil normal.	2. Pupil small, gray, sluggish, irregular after use of atropine.
3. Anterior chamber normal.	3. Exudation in anterior chamber.
4. Conjunctival injection, coarse meshes, most pronounced in fornix and fading toward the cornea.	4. Ciliary (circumcorneal) injection; pink zone of fine vessels surrounding cornea and fading toward fornix.
5. Mucous or muco-purulent secretion.	5. Lacrymation, but no secretion.
6. Discomfort, but no real pain.	6. Pain, worse at night.
7. Conjunctiva reddened and opaque.	7. Conjunctiva usually transparent.
8. No interference with vision.	8. Vision diminished in acuteness.

(May's *Diseases of the Eye.*)

5. ABDOMINAL PAINS IN THE MALE. (1) *Over the diaphragm,* may be due to pleurisy. (2) *More or less general, and sharp or colicky,* may be due to gastralgia, cancer or ulcer of stomach, enteralgia, enteritis, lead colic, arsenical or mercurial poisoning, floating kidney, mucous colic, flatulence, intestinal obstruction, intestinal perforation, onset of appendicitis, peritonitis, hernia, pancreatitis, locomotor ataxia, diabetes, Raynaud's disease. (3) *In right hypochondriac region,* cancer cirrhosis or inflammation of liver, aneurysm of abdominal aorta, subphrenic abscess. (4) *In left hypochondriac or lumbar regions,* renal colic, pyelitis, movable kidney, enlarged spleen, impacted colon, gastric dyspepsia, gastroptosis, gastrectesia. (From Butler's *Diagnostics of Internal Medicine.*)

6. In *renal colic:* The pain is in the region of the affected kidney; it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In *hepatic colic:* The pain is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

7.

AORTIC DISEASE.	MITRAL DISEASE.
Symptoms are mainly due to anemia, viz.:	Symptoms are mainly due to venous congestion, viz.:
1. Pallor.	1. Cyanosis.
2. Throbbing of the carotids.	2. May get pulsation in the veins of the neck.
3. Attacks of an "angina pectoris" type of pain.	3. Sudden attacks of severe dyspnea—actual acute pain is rare.
4. Breathlessness on slight exertion.	4. Breathlessness, but often present without exertion.

AORTIC DISEASE.	MITRAL DISEASE.
5. Nervous symptoms are prominent, owing to cerebral anemia. Syncopal attacks are also common.	5. Pulmonary symptoms are most prominent, *i. e.,* cough in the morning, chronic bronchitis, hemoptysis, dilated right side of heart, and later symptoms due to tricuspid leakage.
7. The *left ventricle* is usually much hypertrophied.	7. The *left auricle* is somewhat hypertrophied, but the main hypertrophy is that of the *right ventricle.*

(From Wheeler and Jack's *Handbook.*)

9. The *causes of endocarditis* are: Rheumatism, chorea, the acute infectious diseases (chiefly scarlet fever, diphtheria, and pneumonia), septicemia, tuberculosis, gonorrhea, nephritis, alcoholism, syphilis, gout.

PATHOLOGY.

1. *Etiology of thrombosis:* Changes in the blood current; changes in the blood; changes in the vessel wall; anything within the circulation not covered by endothelium. Generally two or more of these conditions are present.

3. "It is estimated that about one-third of the fecal matter of adults, if dried, would be found to consist of bacteria." (Williams' *Manual of Bacteriology.*) Hence, 33 per cent. On the other hand, "Kleyn estimates that 1.13 per cent. of the dry feces is made up of microorganisms." (Fischer's *Physiology of Alimentation.*) It is safe to infer, therefore, that it is unknown.

4. By *blood smears,* diagnosis can be made of: Malaria, relapsing fever, filariasis. By *blood culture,* of: Typhoid fever. By *blood count,* of: Pernicious anemia, secondary anemias, leukemias. By *serum reaction,* of: Typhoid fever, Asiatic cholera, Malta fever, glanders, plague.

5. In BANTI'S DISEASE. The *blood* shows a profound anemia; the red cells are greatly diminished; they are a little smaller in size, but their shape is preserved; there is a great reduction in hemoglobin; the white cells are increased in number.

The *gross post-mortem findings* are: Enormously enlarged spleen, with thickened capsule and darkened color; the pulp seems to have disappeared, cirrhosis and atrophy of the Malpighian bodies are noticeable, and there is fibrosis of the spleen. The liver is pigmented and cirrhosed; the heart is dilated and may be flabby.

7. *Tonsillar infection may be followed* by: Rheumatism, endocarditis, chorea, pericarditis, albuminuria, middle ear disease, scarlet fever, diphtheria.

8. *Arteriosclerosis may cause death* by: Bursting of the blood-vessel; the development of thrombosis in the coronary or cerebral arteries; gangrene of the extremities; angina pectoris; chronic interstitial nephritis.

BACTERIOLOGY.

1. (*a*) *Endogenous infections* are those due to the activity of microorganisms which are habitual to the body and are usually harmless.

Exogenous infections are those due to the admission to the tissues of microorganisms from without.

(*b*) The Colon bacillus is an organism associated with endogenous infection; the gonococcus, with exogenous infection.

2. (*a*) The organism of chancre is the *Spirocheta pallida,* also called the *Treponema pallidum.*

(*b*) It is a slender spirillum, with regular turns, about 4 to 20 mikrons long, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

(*c*) The organism of chancroid is the bacillus of Ducrey.

3. (*a*) *Two methods of animal inoculation:* Subcutaneous and intravenous.

(*b*) *Precautions necessary to satisfactory results:* The hair should be removed from the site of the inoculation; asepsis must be practised at every stage of the process; the animal must be treated with the utmost gentleness, and shock must be prevented or treated; the animal should be isolated, and medication of all kinds must be avoided.

4. *Bolton's method of preparing potato for cultural purposes,* is as follows: The potatoes are washed, a slice is removed from each end, and with an apple-corer or cork-borer a cylinder is cut out. This cylinder is divided diagonally into two pieces. The pieces are washed in running water for several hours. They are placed in test tubes containing a little water to keep the potato moist, and are supported from the bottom on a piece of glass tubing about 1 to 2 cm. in length (or on cotton, or in a specially devised form of tube with a constriction at the bottom). The tubes are plugged and sterilized as with other media. Sterilization, however, must be thorough on account of the danger of contamination with the extremely resistant spores of the potato bacillus. Potato is best when freshly prepared; it is likely to become dry and discolored with keeping. It is a very useful medium; certain growths on it, like those of the bacillus of typhoid fever or of glanders, and those of chromogenic bacteria, are very characteristic.

5. (*a*) *Three pyogenic organisms: Streptococcus pyogenes, Staphylococcus pyogenes aureus,* and *Staphylococcus pyogenes albus.*

(*b*) *Three toxine producers:* Bacillus of tetanus, Klebs-Loeffler bacillus, and Eberth's typhoid bacillus.

(*c*) *Five pathogenic microorganisms positive to Gram's method:* Bacillus of diphtheria, bacillus of tuberculosis, bacillus of anthrax, *Streptococcus pyogenes,* and bacillus of tetanus.

6. The most frequent causal organism in: (*a*) Appendicitis, is *Bacillus coli communis,* or the staphylococci; (*b*) acute cystitis, is *Bacillus coli communis,* or gonococcus.

7. (*a*) *Three anaërobic bacteria:* Bacillus of tetanus, bacillus of symptomatic anthrax, and bacillus of malignant edema.

(*b*) For the cultivation of anaërobic bacteria, Archinard gives the following method: A culture tube three-fourths full of the medium is heated to the boiling point and allowed to cool to a temperature in the neighborhood of 40° C.; then a platinum needle charged with the material for inoculation is dipped down to the bottom of the tube. With fluid media, immediately thereafter a layer of paraffin oil is poured on the surface of the liquid before introduction of the cotton plug. With solid media the fluid is allowed to solidify after inoculation, and after solidification the paraffin oil is poured on the surface of the medium. This effectually shuts out the oxygen, and as a rule allows a luxuriant growth of anaërobic bacteria.

8. (*a*) *Leucomains* are basic nitrogenous substances produced in living tissues.

(*b*) *Pleomorphous* bacteria are such as assume more than one form.

(*c*) *Agglutin* is something in the blood serum of an animal affected with a bacterial disease which is capable of causing the clumping of the bacteria which cause the disease.

(*d*) *Alexins* are defensive bodies which exist normally in the blood serum.

(*e*) *Phlogistic* means inflammatory.

OBSTETRICS.

1. A *four months' fetus* is about four to seven inches long, weighs on an average two ounces; the length of the head is one-fourth that of the body; the cranial bones are partly ossified, but show very wide sutures and fontanelles; the face is distinct; mouth, nose, eyes, and ears have their proper shape; the sex can be distinguished; the skin is moderately firm, and hair begins to develop. (From Witthaus and Becker's *Medical Jurisprudence.*)

6. Many authorities do not consider that frights, accidents, etc., in a pregnant woman have anything at all to do with birthmarks or monsters. The cause of these abnormal cases is not known; arrested development, errors of development, and partial destruction of embryo, together with pathological conditions in membranes, amniotic fluid, or fetus *may* be etiological factors. All that a physician can do is to try to put the patient in good hygienic condition and remove all disturbing influences.

GYNECOLOGY.

5. (*a*) *"Vicarious menstruation* is a flow of blood from some organ (other than the uterus), recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, the nails, the mammary glands, ulcerated surfaces, and many other parts." (King's *Manual of Obstetrics.*)

(*b*) *Supplementary menstruation* means a menstrual flow from the uterus and also from some site (as given under vicarious menstruation).

(*c*) *Suppressed menstruation* is a form of amenorrhea in which the patient has formerly menstruated, but menstruation now fails to appear.

(*d*) *Emansio mensium* is a form of amenorrhea in which menstruation has *never appeared. Two causes:* Imperfect development or absence of the uterus, and atresia of the vagina.

6. In *incomplete laceration of the perineum* any of the following tissues may be lacerated: Skin, mucous membrane of fourchette, Constrictor vaginæ, Transversus perinei, and Levator ani.

In *complete laceration* the sphincter ani and the anterior surface of the rectum are involved, in addition to the structures named above.

LIFE INSURANCE IN ITS RELATION TO THE PREVENTION OF TUBERCULOSIS.*

BY S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF PHTHISIO-THERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; ATTENDING PHYSICIAN TO THE RIVERSIDE HOSPITAL SANATORIUM FOR THE CONSUMPTIVE POOR OF THE CITY OF NEW YORK, ETC.

To judge from the cordial invitation extended to me by the Secretary of the American Association of Medical Examiners to appear before you again and talk to you on the Prevention of Tuberculosis and the Relation of Life Insurance Thereto, it seems that the time has come for active cooperation between life insurance companies and existing antituberculosis agencies. The only question concerning which there seems to be some doubt is as to how this cooperation can be effected and be of mutual advantage to the companies, of which you are the medical representatives, and to the policy holders.

Those of you who have read the recent admirable article by Mr. Frederick L. Hoffman, on "The Relation of Life Insurance to the Problem of Tuberculosis Prevention,"† will acknowledge that there is as yet by no means a unanimity of opinion regarding this vital point. What distinguishes Germany from America in its antituberculosis crusade is the existence of a system of compulsory insurance. According to Mr. Hoffman and others, compulsory insurance against disease in this country is a political impossibility, and voluntary insurance against tuberculosis would result in business failure.

Mr. Lee K. Frankel, the manager of the industrial department of the Metropolitan Life Insurance Company, one who has given this subject careful study, does not seem quite to agree with Mr. Hoffman. In a letter received from him on May 24, he reiterates to me the opinion which he had expressed in a paper on "Health Insurance for Consumptives," read at the New York State Charity Conference of 1901. I quote the exact words from his letter: "I am of the opinion, as I was at the time (May, 1901), that a sickness society or an association which insured against sickness, with particular reference to tuberculosis, could become an accomplished fact. Such a company might probably not be able to do more than to insure its members against sickness. The only important question which really arises is the amount of premium which they would have to charge."

To this, as well as to Dr. Arnold C. Klebs' proposition, made in 1906 in his paper, "Insurance of Industrial Working Men as an Instrument of Tuberculosis Prevention," and also to my similar proposition made in 1902 before the National Conference of Charities in Detroit, as well as in 1907 before your association, Mr. Hoffman replies categorically by saying: "I am fully convinced, after a very careful investigation, that as a financial proposition the treatment of tuberculous policy-holders by American life insurance companies in special institutions for their cure, is absolutely impossible. This applies also to the organization of special societies or companies for the exclusive insurance of tuberculous policy-holders. . . . . I repeat that, in my opinion, the true problem is one of *prevention* and not of cure, and one of the most useful additions to our knowledge would be a comprehensive and strictly scientific investigation into the diseases of occupation with special reference to consumption and the pathology of dust in its relation thereto."

Before taking up the side of the subject on which Mr. Hoffman disagrees with Mr. Frankel, Dr. Klebs, and myself, I desire for a moment to talk on a subject concerning which we all three do so emphatically agree, namely, the problem of prevention. How much can be done in this direction by the life insurance companies who are in earnest concerning this work, is something of which even the most sanguine of those of us interested in the combat of tuberculosis as a disease of the masses can hardly conceive.

Here is what a single company purposes to do in the direction of the eradication of tuberculosis among its policy-holders. Not to make any unwarranted statements, I asked Mr. Frankel to reply to me precisely what his company was going to do. The letter received from him as an answer to my inquiries reads as follows:

NEW YORK, May 24, 1909.

"MY DEAR DR. KNOPF:—

"I have your favor of May 22nd, in which you ask for an authoritative statement of what the Metropolitan Life Insurance Company purposes doing in the direction of the eradication of tuberculosis among its policy-holders.

"In reply, I am saying that we have at present in preparation a condensed treatise on the nature, extent, cure, and prevention of tuberculosis, which we intend distributing among our industrial policyholders. While this in itself would be a distinct educational campaign, we think that the mere distribution of this pamphlet will not suffice. For this reason we are asking the policy-holders in the pamphlet to notify us in case they should either at present or in the future be victims of tuberculosis. We purpose as soon as we receive replies from them to put them in touch with the agencies in their respective communities, if there are any, so that they may obtain the necessary treatment. Our agents in the field are receiving similar instructions, so that

*Address delivered by invitation before the American Association of Medical Examiners, at the Meeting in Atlantic City, June, 1909.

†*Medical Examiner and General Practitioner*, March, 1909.

when they find policy-holders on their weekly visits who are tuberculous, that they may in conjunction with the Home Office endeavor to bring the policy-holder in touch with the particular society, hospital, dispensary, sanatorium, or day-camp where he may receive treatment.

"As you know, we have advertised somewhat extensively the offer on our part to place at the disposal of all antituberculosis associations, health officers, sanatoria, etc., the machinery of our agency staff for the distribution and dissemination of any literature or information of any of these organizations."

In justice to Mr. Hoffman I wish to say here that I believe it was he who originated the thought of using life insurance institutions for the purpose of antituberculosis propaganda. It was my privilege in 1901 to vote on a resolution which he presented before the British Congress on Tuberculosis in London, which was to the effect that "life insurance companies and societies by means of publications, or otherwise, should give the largest possible amount of publicity to the most essential and most easily comprehended facts of preventive treatment and cure of tuberculous diseases."

I have not yet seen the antituberculosis pamphlet prepared by Mr. Frankel, but I am sure from what I know of Mr. Frankel's painstaking work that it will be a model in every respect. It will describe all the four sources of infection—inhalation, ingestion, inoculation, and droplet infection—and the methods to prevent them. It will describe the early symptoms of tuberculosis which can be detected by laymen, and urge upon them the need of seeking medical advice when suspicious symptoms manifest themselves. It will teach the value of fresh air day and night, the dangers of intemperance in all things, and that a normal, healthful life in normal, healthful surroundings is the best guarantee not to become tuberculous. It will teach how to overcome an hereditary as well as an acquired predisposition. It will teach that tuberculosis can be best treated by hygienic and dietetic means, in pure air, under constant medical supervision; and that patent medicines, advertised "sure consumption cures," and whiskey as a preventative or as a curative means, are not to be relied upon. In short, it will teach the preventability as well as the curability of the disease and, last but not least, will teach that the trained, honest, and conscientious consumptive can be associated with as safely as anyone else, and that to shun him is cruel and unkind. In this pamphlet the phthisiophobiac will be taught not to fear the consumptive, but to love and have compassion for him.

So much for what the policy-holders can learn from such a pamphlet. But the agents of the life insurance companies should know a little more if their work is to be truly effective. They must do a little more than merely to distribute the leaflets to their clients. The agent visiting the family of a policy-holder can, indeed, be a great power of good if he supplements the printed pamphlet by verbal instructions. To this end he must not only know by heart all that is contained in the pamphlet, but he must know a little more of hygiene and ventilation at home, and in factory, and workshops, than the average layman. He must have studied the social aspect of tuberculosis and all its predisposing causes. It is in this way that the humble agent of a life insurance company can become a veritable savior of man. The greater the love and earnestness which he puts into his calling and the more he is able to practically demonstrate his teachings by personal conduct and appearance, the greater will be his results. He can indeed be a tremendous power for good, not only in the solution of the tuberculosis problem, but in the social problem at large.

Such an agent must constitute himself not merely a friendly visitor, but a friend of the family, and while in the event of sickness he will naturally refrain from attempting to give medical advice, in the event of tuberculosis he has a perfect right, nay, even a duty, to urge the greatest precautionary measures so that new centers of infection may not be created. If it is advisable he may, by cooperating with the family physician, refer the tuberculous invalid to the proper local antituberculosis agencies, as mentioned by Mr. Frankel.

The investigation of the causes of tuberculosis which must be traced to occupations, concern the individual agent only when the workshop and domicile of the patient are one. The work which lies before him here is obvious and need not be detailed. The large problem of studying and preventing disease, and particularly tuberculosis contracted in factories and various industries, would seem primarily a matter for the government to undertake; but we all know how very welcome and helpful private investigations are and what benefit to the masses is thereby often produced.

To my mind, there seems to be no earthly reason why the study of factory hygiene and the prevention of occupation diseases, inaugurated by the Prudential Life Insurance Company under Mr. Hoffman's brilliant direction, should not be imitated and enlarged upon by all companies willing to do it. That to the companies considerable financial, and to the policy-holders considerable physical and moral benefit must accrue through such work, is evident. Professor Irving Fisher's recent eloquent plea for concerted action on the part of life insurance companies to lend their financial aid to the cause of preventive medicine, is certainly a wise and timely one.

I return now once more to the subject of treatment, and I confess that I am somewhat amazed at Mr. Hoffman's statement, already quoted above, wherein he says that in his opinion the true problem is one of prevention and not of cure. Does Mr. Hoffman forget that the two go hand in hand, and that when Mr. Frankel, Dr. Klebs, and I appealed to the insurance companies to help in the cure of the patients, what we had in mind was also very largely preventive work? Are not sanatoria for the cure of tuberculous patients the greatest existing factors in the prevention of the disease? By taking an individual who is tuberculous into an institution, a center of infection is suppressed. When discharged as cured or improved, the patient trained in all the prophylactic measures becomes a hygienic factor and a teacher in the community to which he returns.

Last, but not least, the sanatoria themselves are preventive factors in communities where they are established. Examples of this we have in the villages of Goerbersdorf and Falkenstein in Germany, Rutland and Saranac Lake in the United States, and of Gravenhurst in Canada, where the mortality from tuberculosis among the villagers has been reduced by one-fourth or one-third since the establishment of the sanatoria. The villagers have consciously or unconsciously learned from the sanatorium inmates cleanly, healthy, and preventive

habits. Surely every consumptive cured in the sanatorium, or under treatment combined with careful training outside of an institution, means more than one human being saved from contracting the disease.

In a communication received from the Metropolitan Life Insurance Company it would seem that at least this institution agrees with me on this point and is willing to try the experiment. Here is the communication from Lee K. Frankel, Ph.D., manager of its industrial department:

"If the law permits it, it is the purpose of the company in the near future to erect a tuberculosis sanatorium which primarily shall be for the treatment of the employees of the company, and if experience warrants it and justifies it, for the treatment of policy-holders. I need hardly say that no one sanatorium would be sufficient for the treatment of all tuberculous policy-holders of the company, and we shall always find it necessary to cooperate with the existing institutions, sanatoria, etc., to secure necessary treatment."

If the Metropolitan Life Insurance Company is able to carry out its project, I am so convinced of its success and so sure that other companies will follow its example that I believe there will be no more need for me to plead for insurance of predisposed or incipient tuberculous adults or insurance against tuberculosis in healthy adults. However, in spite of Mr. Hoffman's criticism, in the March number of the *Medical Examiner*, that the suggestion I made in 1902 to insure the children against tuberculosis was impracticable, I will renew to-day my plea for the children and somewhat enlarge upon this topic.

Tuberculosis is so prevalent that all students of the subject now freely admit that hardly any one of us passes through life without having had at one time or another a little tuberculosis in our system. The majority of children, whether they contract tuberculosis from bovine or human sources, contract it in early life—the first two years. It very often then becomes latent or cured. When it manifests itself, it does so between the ages of 6 and 14—the school age. It is during these years that the morbidity and mortality of tuberculosis is greatest among children. Of course, we know that the badly ventilated or dusty school room, the overtaxing of brain and nervous system to the detriment of the physical welfare of the child, is largely responsible for this fearful condition. We would, of course, not exclude as a strong predisposing cause, the underfeeding and bad housing of some of the children at home. But because we know the reasons of the fearfully great morbidity and mortality from tuberculosis among children, is it not all the more our duty to work for the prevention and cure for the child of to-day which will be the man of to-morrow?

Mr. Hoffman, in his gentlemanly criticism of my proposition to insure children against tuberculosis at 50 cents a month from the birth of each child, which would give to the insurance companies at the end of fifteen years, with accrued interest, a capital of $150, says that I had "overlooked the fact that it would be practically impossible to induce the mass of people to contribute to institutions for the treatment of disease from one particular cause, however common that cause might be." Mr. Hoffman was probably right in making this statement as applied to conditions some years ago; but if he had the chances which I have and all those of us have who constantly work in tuberculosis, he would be amazed what an awakening there is to-day among the people as to the dangers of tuberculosis to themselves and their children. Many would gladly pay 12½ or even 25 cents a week to feel that if their child should ever contract tuberculosis, it would be given at once the best possible chance of recovery. This desire to protect the child from falling a victim to the Great White Plague will be tenfold increased in those parents who are themselves afflicted. But I can assure Mr. Hoffman that the very masses who avail themselves of industrial insurance facilities are now keenly alive to what it means and what it costs to have a tuberculous child or to become a tuberculous invalid, and that whatever sacrifice is made in the line of insurance will amply be repaid when the White Plague knocks at the door.

In 1902, at the time I ventured the suggestion of insurance of children against tuberculosis and pleaded for timely sanatorium treatment in case they contracted the disease, I collected, for an article entitled "The Antituberculosis Movement in the United States in 1902"* the following statistics: Five states and five cities had societies for the prevention of tuberculosis. There was no national association. To-day, there exist in the United States 290 antituberculosis associtaions, and our National Association for the Study and Prevention of Tuberculosis, only five years in existence, has a membership of 2,100. In 1902, throughout the states we had about 60 tuberculosis institutions; to-day, our association's efficient secretary, Dr. Livingston Farrand, reports the existence of 298 institutions, hospitals, or sanatoria where patients are housed, boarded, and kept under constant medical supervision.

At the time I made the above mentioned report, New York was the only city which had a special tuberculosis dispensary. To-day, there are no less than 222 tuberculosis dispensaries throughout the United States. Compulsory notification of tuberculosis was tried in New York in 1904 as an experiment and was met by considerable opposition by some of the most prominent New York physicians.

What is the status of this all-important question to-day?

Twelve States, including the District of Columbia, have special laws regarding the reporting of tuberculosis. Nine States require the reporting of tuberculosis by including the disease with other infectious or contagious diseases. Total: 21 States.

Thirty cities have passed special ordinances requiring the reporting of tuberculosis. Fifty cities have ordinances or regulations requiring the reporting of tuberculosis, including it in the category of contagious and infectious or dangerous diseases. Total: 80 cities.

Five cities request the reporting of tuberculosis.

Of the State laws now on statute books requiring the reporting of tuberculosis, nine have been passed since January 1, 1908; all of them special Acts, dealing with tuberculosis only. Ten cities have made the notification of tuberculosis compulsory since January 1, 1908.

In 1904 there was held in Baltimore the first tuberculosis exhibition in the United States; in 1906, New York created a second tuberculosis exhibit. Since then a traveling tuberculosis exhibition has been created by the National Association

*"Tuberculosis," official organ of the International Tuberculosis Association, Vol. I, Heft 8, August, 1902.

for the Study and Prevention of Tuberculosis, and it has visited nearly every State of the Union. Smaller permanent exhibits are seen in the various large cities. The International Tuberculosis Congress Exhibition, which was shown in New York, Washington, and Philadelphia, and which has been visited by millions of people, must still be fresh in your memory as well as the impulse it gave to the antituberculosis movement in this country.

Surely, after this awakening of the public mind to the situation, I may venture to say that an insurance company which will start the insurance of children against tuberculosis is bound to meet with success. Of course, the special education of the masses concerning the prevention of tuberculosis in childhood must also become a part of the duties of the insurance agent, and the propaganda for more rational curricula less detrimental to the physical development of our children, more playgrounds, more seaside and more inland sanatoria for the treatment of tuberculous children, more open air schools and more outdoor instructions in general, must form part of the public prophylaxis and care to which life insurance companies in general should give their moral and financial support.

I do not believe it is wise to prophesy the eradication of tuberculosis within so short a period as some enthusiasts have recently proclaimed. But, on the other hand, I am convinced that with the life insurance companies to help in the prevention and cure of tuberculosis not only in the adult, but particularly in the child, the time for the eradication of the disease may be brought much nearer. I do not believe in the hue and cry against soulless corporations. Insurance companies are corporations. They are in the business for whatever money they can make; but by helping to educate and awaken the masses to the danger of tuberculosis, by using their agencies to prevent the spread of the disease, and eventually also by creating sanatoria and aiding existing ones, curing thus a goodly number, they are doing the greatest humanitarian work. If in addition they will use their surplus earnings for the building of model tenements in cities, or individual model homes in suburbs or country for laboring men, they will be one of the greatest factors in the reduction of other diseases as well as tuberculosis, and in improving the social conditions of thousands of honest workers, thus doing away with much of the social misery and social discontent of our times.

It has been my privilege during the past year to come in contact with the officers of various insurance companies, and it has been my equally great privilege to address, on one occasion, several thousand insurance agents on what I conceive to be their sacred duties in this holy war against the Great White Plague. The eagerness and earnestness with which they listened, the enthusiasm they manifested when they were invited to cooperate, has ever since been an inspiration to me. I know now that there are insurance corporations and insurance employees who have souls, and I also know that you who are associated with them as physicians and advisors, will know how to inspire them to great deeds and will lead them on to victory over the Great White Plague.

Simulated Tenderness.—To differentiate a tender spot from a simulated pain, it will often be observed that pressure on the former causes a decided increase of pulse rate, while in simulation it does not.—*American Journal of Surgery.*

PELLAGRA, WITH REPORT OF NINE CASES.*

By EUGENE D. BONDURANT, M.D.,

MOBILE, ALA.

PROFESSOR OF NERVOUS AND MENTAL DISEASES, UNIVERSITY OF ALABAMA; MEMBER BOARD OF TRUSTEES, ALABAMA INSANE HOSPITALS.

Pellagra is a toxemic disease of endemic occurrence, very common in Italy and other countries adjacent to the Mediterranean Sea. It is thought to be caused by eating fermenting or otherwise damaged corn meal. Its development is favored by insufficient and unsuitable food, unhygienic surroundings, and a warm and moist climate.

The disease is clinically characterized by gastrointestinal disorders, salivation, general malnutrition with emaciation, a rough, erythematous inflammatory thickening of those parts of the cutaneous surface exposed to sunlight, and by serious disturbance of the functions of the peripheral nerves, spinal cord and brain. The disease in its more acute form runs its course in a few weeks to a few months. The mortality, especially in the acute form, is high. Recovery occurs but relapses are frequent. Many of those who develop pellagra are committed to hospitals for the insane, on account of the associated mental disorder.

Pellagra had until recently been unknown in the United States. The circumstances of its first recognized appearance were these: The Alabama State Insane Hospital for negroes, located at Mt. Vernon, Mobile County, was opened in 1901, several hundred patients being transferred to the institution from the Insane Hospital at Tuscaloosa. During the succeeding four years there occurred during the summer months occasional cases of gastrointestinal disorder presenting some peculiar features, which were thought to be scurvy-like in character, and resulted in efforts toward the improvement of the dietary. During the summer of 1906 the cases of gastrointestinal trouble and malnutrition became so numerous and so fatal, and presented such unusual and in themselves characteristic features, as to convince the medical staff that they had a new clinical problem to deal with. After long-continued study and observation of the cases in the institution, the assistant physicians of the Mount Vernon Hospital, Drs. Geo. H. Searcy, E. L. McCafferty, and J. H. Somerville, made the diagnosis of pellagra. In view of the facts that at that time the disease had never been known to develop in this country, and that our text-books and reference books either made no note of the disease or dismissed the subject, after brief consideration, with the statement that pellagra was not met with in the United States, this was a good piece of diagnostic work and, as such, is entitled to recognition.

A preliminary report upon this epidemic of pellagra was made by Dr. Geo. H. Searcy to the Medical Association of Alabama at Mobile in April, 1907, and immediately attracted the attention of the medical world. A few months later the report of Babcock and the resident staff of the South Carolina State Insane Hospital at Columbia fully confirmed the work of Searcy and his associates. Since then the additional reports of Searcy, McCafferty, and Rudolph, and the corrobative work and observations of Wood, Campbell, Randolph and others have demonstrated beyond peradventure that pellagra not only occurs in the Southern United States, but that

*Read by title at the meeting of the American Neurological Association, New York City, May 27-29, 1909.

it is by no means uncommon, that it is widely distributed, and that the problem of its etiology, pathology, prevention, and treatment is of sufficient practical and present importance to merit the attention of all of those interested in the eradication and cure of preventable disease.

Pellagra was, in this country, first recognized in insane hospitals. The nervous symptoms are prominent and characteristic and it is reasonably certain that many of the cases will fall into the hands of the neurologist and alienist for treatment—facts which have led me to believe that the subject might prove interesting to the members of the American Neurological Association.

My own experience with the disease has been as follows: My duties as trustee take me to the Mount Vernon Hospital from time to time. On one or two of these occasions during 1906 I was shown cases of the puzzling disease. I did not recognize its nature, but expressed the view that it was a scurvy-like condition, probably due to faults in diet and sanitation. I contributed nothing material toward the making of the correct diagnosis, but I did become interested in the disease, obtained pathological material from fatal cases for microscopic study, and in October, 1907, after the disease had been recognized as pellagra, went to Mount Vernon and made a postmortem examination in a fatal case, taking portions of the central nervous organs, the skin, stomach, intestines, liver, spleen, heart, kidneys, and muscular tisse for pathological study.

I also began a careful study of the cases of nervous disease coming into my hands for treatment to determine the question of the occurrence of pellagra outside of the insane hospitals. Nearly a year passed, however, before anything resembling it appeared in my private work. Then, in the late summer of 1907, a patient (Case I) was sent to me by one of my up-country friends for treatment for "some spinal trouble," and the case was at once recognized as presenting the same clinical picture as did those at Mount Vernon. In January, 1908, the second case was seen and then from August, 1908, to March, 1909, seven more cases of pellagra occurred in my practice. These nine cases are briefly reported below:

Case I.—Female, aged 19. Had poliomyelitis anterior five years ago which left the left leg in a condition of partial paralysis. Has lived on a farm and suffered some from malaria. In the summer of 1906 she became nervous and neurasthenic, but improved during the winter. With the oncoming of hot weather in 1907 she grew worse again. Had for several months been despondent, easily irritated, restless. Has shown "nervous twitchings" in muscles of face and upper extremities. During the same period has had indigestion and has slowly lost in weight. Has not menstruated in three months.

August, 1907.—She is pale and sallow, but not greatly emaciated. Urine contains casts and a trace of albumin. Blood shows no malarial parasites; hemoglobin, 85 per cent. Tongue is red, moist, coated in center, breath offensive. Patient expectorates continually, has gaseous eructations, complains of tenderness in the pit of the stomach, has no appetite, is now constipated, but has had attacks of diarrhea.

The skin of the backs of the hands, knuckles, elbows, and dorsal surface of feet is rough and was "red early in the summer," her mother says. The left lower extremity is smaller, shorter, and colder than the right, muscles atropied, marked contracture; tendon reflex is absent (this condition due to an earlier poliomyelitis). In the right lower extremity and in both upper extremities the tendon reflexes are exaggerated and fibrillar twitching is marked. Muscular strength slight, sensation unimpaired, special senses normal. Speech somewhat slurring and indistinct, conspicuous twitching of muscle fibers in tongue and lips. The mental state is one of mild depression, with emotional instability and a general lowering in intelligence.

The patient grew slowly worse, vomited her food, had irregular rises of temperature. Mental state became one of dementia and extreme despondency. Emaciation was extreme. Toward the close the backs of the hands and wrists as well as the feet and ankles showed a rough, red sunburn-like erythema. The patient died four months after she came into my hands. She had probably had the disease for eighteen months at least.

Case II.—Man, 47 years old. Gives a history of dyspepsia, excessive salivation, diarrheal attacks, general ill health, and nervousness extending over several years—better in winter, worse in summer.

Jan., 1908.—Is emaciated and weak; tongue red, much secretion of saliva, complains of indigestion, and has diarrhea; nothing agrees with him. Skin of hands, wrists, and especially knuckles red, rough, and cracked; has occasionally been that way for several years, he says. Patient is despondent, apprehensive, self-centered, restless, a little demented. Is tremulous, weak, and keeps to his room, although not continually in bed. Fibrillar twitching of the muscles of lips and tongue is well shown; all tendon reflexes are lively; sensory disorders are not demonstrable. Patient remained unchanged for a month or two, then grew worse and died. This was a chronic case of indefinite duration—probably a number of years.

Case III.—White woman, age 40, married, and has ten children. Had severe indigestion about twelve years ago, lasting two years. Three years ago began suffering from indigestion again, and has not been free from it since. Has lost forty pounds in weight, has had repeated attacks of diarrhea, has grown very melancholy and apathetic. August, 1908. The skin of the knuckles and wrists is rough and red. Muscles are weak and the least exertion is very prostrating. Fibrillar tremor is shown in lips, tongue, and extremities, tendon jerks are exaggerated, voice is tremulous, and articulation is impaired. Mental state, a mild melancholia with distinct dulling of intelligence.

This patient has improved a little since she first came under observation sixteen months ago, and is at last report "holding her own" at least.

Case IV.—White woman, age 36. Brought to the Inge-Bondurant Sanatorium for treatment in August, 1908, in a condition of extreme physical and mental weakness, and died five days later.

She had had an attack of "nervousness" two years ago—a neurasthenia, from which she apparently recovered. Last summer she was again nervous and ailing, had "bowel trouble," but grew better in the fall. This summer she again got sick, had "stomach and bowel trouble," lost in weight, became unusually nervous, despondent, and then feeble minded and delirious. Became too feeble to walk several weeks ago. At the time she came into the sanatorium she was confused, delirious, disoriented, incoherent. Lips and tongue tremulous, twitching in muscles of extremities, tendon jerks

lively; no satisfactory test of sensation possible. The skin of the hands, wrists, knuckles, and elbows was rough, dark red, dry, and harsh.

This patient probably suffered from pellagra one and possibly two years, if the attack of "nervousness" in the summer of 1906 can be regarded as an early manifestation of the disease,

Case V.—Woman, aged 39. Brought to me in December, 1908, for treatment for mental disorder. Has been growing nervous, eccentric, and abnormally religious during several years, and shows distinct religious, self-condemnatory, and persecutory delusions for the three months past. Has been in bad health, lost in weight, suffered from dyspepsia and diarrhea.

There is a typical rough red, pellagrous erythema on backs of hands, wrists, knuckles, elbows, and malar eminences. Tongue and oral mucous membrane are red; salivation is abundant; slight rise of temperature. Blood: hemoglobin 70, no corpuscular abnormalities. Urine contains a trace of albumin and some finely and coarsely granular casts, sp. gr. 1.020, daily quantity small. Patient is emaciated and cachectic. Mental state is one of religious exaltation with delusions and auditory as well as visual hallucinations. Muscular strength is greatly diminished. There is a coarse tremor in upper extremities; fibrillar tremor of lips and tongue; twitching in isolated muscle groups in the lower extremities. Sensory disorders not elicited; special senses normal. All tendon reflexes are exaggerated.

The patient was sent to the sanatorium and was put to bed. She ran an irregular and not characteristic rise of temperature; had no appetite and suffered from gastric inefficiency. Salivation was marked. The mental disorders soon assumed the character of a babbling delirium. Weakness, muscular twitchings, and incoordination, as well as reflex exaggeration, increased. Toward the end the patient became stuporous. She died four weeks after admission to sanatorium.

Case VI.—Woman, aged 37, married: has several healthy children, and showed no nervous disorder until the summer of 1908, when she had "malarial fever," bowel disorder, and indigestion. Has never been well since. Was emaciated and has had "stomach trouble." In November, 1908, had "slow fever." With these evidences of physical disease, there were marked nervousness, emotional instability, fits of despondency, irritability, and, following the attack in November, a development of religious fervor and enthusiasm which soon eventuated in religious delusions. The patient also became confused, talked a great deal, and showed some incoherence. At times she had persecutory delusions. In this condition she was brought to the Inge-Bondurant Sanatorium in January, 1909, the following symptoms being shown at the time of admission: Emaciation and weakness marked. Temperature, 99.5° F. Blood: Hb, 85; no parasites nor corpuscular abnormalities. Urine contains numerous casts of all varieties and a small amount of albumin. Is scanty in amount and high colored. Tongue red; salivary secretion abundant; appetite and digestion deficient; evident gastritis; bowels loose. Skin of hands and elbows rough and dark, but no active erytherma. Mental state one of delirium with incoherence, religious ideas dominating. There were conspicuous tremor of lips and tongue, a slurring articulation, fibrillar twitching, and coarse tremor and incoordination in upper extremities, muscular weakness, exaggeration of the tendon reflexes, decided ankle clonus. Sensory and special sense abnormalities not demonstrable.

The patient showed an improvement in the mental state, the talkative delirium subsiding, but there remained some religious delusions and easy excitability. After a few days the delirium returned and continued until it passed into a muttering stupor a few days before death occurred, five weeks after admission. The fibrillar tremor, slurring speech, and reflex exaggeration became more marked as the case progressed. There was a gradual increase in temperature (104° being recorded). There were no parasites in the blood and the fever was unaffected by quinine.

Case VII.—(Seen in consultation with Dr. H. T. Inge). Woman, age 30, married; has healthy children, no previous history of nervous disease. Taken sick during the summer of 1908 with malaria and gastrointestinal disorder. Improved, but in November grew very nervous and weak and began showing mental disorder. At the time of examination she had a typical pellagrous erythema on the hands and face. Tongue and lips were red and raw looking. History of salivation and attacks of diarrhea, together with much indigestion. Mental state: a mild, confusional condition, with apathy, occasional irritability, and excitement—no distinct delusions. There was no sensory disorder. The gait was uncertain, but not characteristic. Muscular weakness noticeable; also fibrillar twitchings and tremor in muscles of extremities, as well as in lips and tongue. Deep reflexes exaggerated; imperfect ankle clonus.

The patient passed into a state of muttering delirium, became more tremulous and weak, and died two weeks after first examination was made.

Case VIII.—Woman, unmarried; good family and personal history. During the summer of 1908 had a severe and persistent chronic diarrhea, with indigestion, salivation, red tongue, nervousness, emaciation, and a rough, red eruption on hands and face. She got better, then had a relapse in the early fall; again improved, to relapse again, and was then brought to me on account of the development of conspicuous mental defect and aberration. When seen, eight months after the onset of the attack, she was emaciated, not anemic, had no malarial infection, no albumin nor casts in the urine. The integument of the hands, forearms, elbows, and knuckles was a little rough and thick, but showed no typical redness. Lips and tongue were red, salivary secretion was abundant, no desire for food, gaseous eructations, vomiting of food, and general gastric discomfort. The patient was oriented as to time and space, but intensely despondent, and showed a continual stream of persecutory and self-condemnatory delusions; she was restless, moaned, exclaimed, and bewailed her condition, her sins, her misfortunes, etc. She was weak, gait unsteady, not spastic, slight tremor of tongue and lips, none in muscles of trunk or extremities, all tendon jerks exaggerated, no ankle clonus nor Babinski sign. The patient remained six weeks in the sanatorium, making no improvement, and was then transferred to the State Hospital for the Insane.

In this case there was a typical history of pellagra, with partial subsidence of the symptoms before the patient came under my care.

A sister of this patient had an attack of pellagra —eruption, gastrointestinal disorder, salivation, nervous and mental disorder, all typical—in the

summer of 1907. She made a complete recovery and showed no evidence of pellagrous disease or nervous disorder at the time she brought her sister (the patient above spoken of) to me for treatment.

Case IX.—Woman, aged 33, married; has three healthy children; family history neurotic. Patient was in good health and free from nervous disorder prior to this attack. In April, 1908, she developed an erythema on the backs of the hands and on the fingers. At the same time her mouth "got sore," as if she was salivated. After several weeks the eruption and the salivation subsided. During the summer she had two relapses—*i.e.* the red eruption on hands and the "sore mouth" returned, to subside again in each instance after a few weeks. During the hot months she had dyspepsia and lost in weight, had repeated attacks of diarrhea; also grew nervous and irritable, had fits of despondency, and in October showed mental impairment with delusions. Since then, with occasional periods of partial subsidence, she has grown slowly worse and for a month past has been delirious.

January, 1909, she shows a typical pellagrous eruption on the hands, wrists, and elbows, and a slight redness and roughness of integument of the malar eminences. Tongue and lips are red, saliva is abundant, there is tenderness in the stomach with gaseous eructations, no appetite; is emaciated. Lips and tongue twitch, articulation is slurring, tremor of hands, and some incoordination. All deep reflexes are exaggerated, no spastic rigidity noted, no Babinski sign, no sensory nor special sense abnormalities. The patient is semidelirious, restless, frets and cries, complains of ill treatment, thinks she is to be killed, accuses herself of misconduct, at times becomes wildly excited and noisy, at other times lies quiet and in a half stupor.

The patient improved rapidly, her mental state became nearly normal, the eruption faded, her gastrointestinal symptoms almost disappeared. She was taken home after a month in the sanatorium. A few weeks after her return home all of the gastrointestinal nervous, mental, and cutaneous abnormalities returned, she lost rapidly in strength, and died two months after discharge from the sanatorium.

The diagnosis in all the above cases was based upon the coexistence of oral, gastric, and intestinal irritation with salivation, indigestion, and diarrhea; erythematous eruption (or history of the same) on hands, face, or elsewhere; mental and nervous disorders indicative of a toxemic irritation of and subsequent degenerative change in the cells of the central nervous organs, notably the cortex cerebri.

In all of these cases the nervous symptoms were most in evidence. My work being limited to nervous and mental disease, it is to be expected that only cases showing nervous disorder would fall under my observation. It is also to be noted that all of these cases were in the last stages of the malady before they came into my hands. Most of them terminated fatally within a week to a few months after I first saw them.

The cases reported are too few in number to warrant the drawing of any general conclusions as to the clinical characters of the associated nervous disorders or of "pellagrous insanity," if it is desirable to employ this term. I feel, however, tempted to make these tentative generalizations: The nervous disorder develops with or shortly after the initial stage of the disease and is in the beginning not characteristic. A neurasthemic symptom complex is frequent. At a later period emotional instability with despondency, often interspersed with periods of excitement, occurs. The delirium-like nature of the mental disorder seems a feature, the psychic symptoms not being readily grouped under any of the usual heads of a classification of insanity. In still later stages some cases suggest an atypical general paresis, the mental defects, slurring speech, and tremulous lips and tongue being a somewhat constant feature. In general, emotional depression predominates, but acceleration of thought processes and exaltation with frequent religious delusions are noted, suggesting in some instances an insanity of double form. A history of remissions and relapses is notably frequent.

Neurotic heredity was not a factor in the above cases. Most of them had previously shown no nervous or mental instability prior to the beginning of the pellagrous disorder.

My belief is that the mental symptoms are those of a toxemic delirium, due to action of poisons upon the nerve cells with eventual progressive degeneration in the cells of the cortex.

The associated nervous disorders, due to disease in the projection neuron mechanism, are chiefly fibrillar tremor and twitching in the muscles of lips, tongue, and extremities, increased muscular irritability, muscular weakness, and probable atrophy, with exaggeration of the deep reflexes. Sensory abnormalities are not conspicuous.

Reference has been made by several recent American writers to certain differences in our cases from those reported abroad, especially to the acute course and high mortality of the American pellagra. I venture to suggest that the seemingly rapid course and early fatal termination in American cases is due to the fact that the incipient and early stages are as yet not often recognized, the diagnosis being made only in those severe and typical cases which have already progressed to a threatened fatal termination before their nature is discovered.

The morbid anatomical changes shown in the three cases from the Mount Vernon Hospital studied by me may be briefly summarized as follows: Inflammatory reaction in the skin, gastritis, enteritis, fatty infiltration and degeneration of the liver, parenchymatous degeneration of the heart muscle, renal epithelium, and the cortical nerve cells. There are also general emaciation, diminution in size of most of the organs, evidences of malnutrition, some fibroid thickening, and arteriosclerosis.

In all of my cases there is the history of the liberal use of corn meal as food, and most often it is claimed that a "good Western meal" is used, or "meal ground from Western corn." At the Mount Vernon Hospital, where the largest number of cases has occurred, Western corn is used exclusively. This corn is shipped in bulk, sometimes becomes "heated" and the meal is in some instances quickly mould-infected and sours readily. I have no evidence to offer as to whether or not the eating of damaged meal is the cause, or the only cause, of pellagra.

As to the frequency of pellagra at this time in Alabama, I will say that the nine cases here reported represent all instances of the disease seen by me from August 1, 1907, to May 1, 1909. During this period—twenty months—I received for treatment or saw in consultation 590 cases of nervous disease. All of my cases occurred among white persons, but since I have practically no negro patients this fact does not indicate any special sus-

ceptibility among the whites. In fact, the statistics of our two State insane hospitals would seem to show a much larger amount of pellagra among the negroes. At Mount Vernon, where the insane negroes are cared for, there have been some 150 cases of recognized pellagra—usual population less than 600. At Tuscaloosa, where the white insane are treated, usual population 1,400, there have thus far been found only about 25 cases of the disease. Randolph, from the Florida State Asylum at Chattahooche, where both white and colored patients are under care, reports a greater amount of pellagra among the whites.

How long has the disease prevailed in the South? My belief is a few years only. The clinical picture of the disease is definite and characteristic and once seen is easily recognized. Nothing resembling it was known at Tuscaloosa during the decade preceding the opening of the Mount Vernon Hospital, when the negro insane as well as the whites were provided for in the Tuscaloosa Hospital. Shortly after the negroes were moved in a body to Mount Vernon the disease appeared and, while its true nature was not recognized, its unusual character at once attracted attention. If the disease had existed it would have been sooner diagnosed.

I have practised in Mobile for eleven years, seeing several hundred new patients each year. Looking over my clinical records and passing my cases in mental review, I can see none in which the diagnosis of pellagra would be justified prior to August, 1907.

I recognize, fully, gentlemen, the superficial character of these studies in pellagra. I record these cases as a small contribution toward the elucidation of a new and seemingly important pathological condition. I bespeak your attention to the disease, for it is those especially concerned in the treatment of nervous and mental diseases who are likely to see most of the cases.

THE VALUE OF MICROSCOPICAL EXAMINATION OF THE PROSTATOVESICULAR SECRETION IN THE DIAGNOSIS AND PROGNOSIS OF GONOCOCCUS INFECTION.*

By ABR. L. WOLBARST, M.D.,

NEW YORK.

CONSULTING GENITOURINARY SURGEON, CENTRAL ISLIP STATE HOSPITAL; ATTENDING GENITOURINARY SURGEON, BETH ISRAEL HOSPITAL AND WEST SIDE GERMAN DISPENSARIES; PROFESSOR OF GENITOURINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE.

It is exactly two years since I had the privilege of reading before this Association a paper, entitled, "A Brief Study of the Prostate, With Reference to the Curability of Gonorrhea."† The conclusions arrived at, in that study of fifty-five cases of chronic gonorrhea, were briefly as follows: That the recurrent and apparently incurable cases of gonorrhea in the male, are those in which the gonococci remain latent in the prostate and its annexa; that the urine passed by the patient may be clear as crystal, and yet gonococci may sometimes be found in it; that even though the urine be clear and gonococci are not found in it, examination of the massaged prostatic secretion will often reveal the presence of gonococci and inflammatory detritus; and lastly, that the examinations must be made repeatedly before we can decide with a reasonable degree of certainty whether or not gonococci are present in the organ. This paper was followed by another‡ in which the same subject was discussed at greater length.

In the last two years, I have had the opportunity of studying fully three hundred cases of male gonorrhea, with particular reference to the tenacity and persistence of gonococci in the prostate. The great majority of these cases have presented no unusual features, and have not been of any special interest in the present connection. Only those cases in which three or more examinations were made, have been included in this paper. I have selected thirty-five cases, for the basis of the present paper, because these cases have emphasized certain features of this subject that are of more than passing interest. From three to nineteen examinations of massaged secretion were made in each of these cases (see Table 1), a total of two hundred and forty examinations. These cases have been divided into two classes: (1) those that showed clinical symptoms and came to be treated for them—twenty-one in number, and (2) those that did not show clinical symptoms, but who came for examination for some other complaint, or for advice preparatory to marriage—fourteen in number.

I feel fortunate in having been able to see so many of the latter class, for apart from the interest inherent in the purpose of their visits, was the fact that they brought home in a most startling fashion, the well-known but apt-to-be-forgotten fact, that once a man has had a gonorrhea involving the deep seated structures, he need not be surprised to find gonococci in his prostatic secretion months and even years after all traces of the disease have disappeared; also that such a man might have gonococci in his prostate for many years without being troubled by them in the least. It is usually stated that gonococci do not survive in the prostate for more than one to three years.§ A survey of Table 2 will show that in the fourteen patients of this division, who did not complain of any symptoms referable to their past gonorrhea, gonococci were found in six (43 per cent); in a total of 95 examinations in these patients, gonococci were found 9 times (9 per cent), and the period that elapsed between the last gonorrhea and the examination varied from six months to eighteen years, an average of about four years. If these figures mean anything, they mean that gonococci may persist in the prostate for much more than three years, and that a fair proportion of the men who have had gonorrhea and who have apparently entirely recovered, still harbor gonococci in the prostate, which might be revealed if a sufficient number of examinations of their massaged prostatic secretions were made.

Note. + represents a positive finding; − a negative.

145 examinations were made in these twenty-one cases, an average of seven for each patient—three examinations being the lowest in any case, and nineteen the highest (case 5). In these 145 examinations, gonococci were found sixteen times (11 per cent), and they were found in ten patients of the twenty-one examined (50 per cent). The duration of the existing gonorrhea varied from two months to twenty years. Most of these patients gave a history of repeated recurrences at more or less frequent intervals, and all gave the typical subjective and objective symptoms of chronic gonorrhea. Some were complicated by stricture, and all of them showed ample evidence of the presence of a chronic prostatitis. It is interesting to note that case 3 in table 2, and case 5, in table 3, had an equal number of examinations made, *i. e.*—19. In the former there were no symptoms of chronic gonorrhea; in fact, though the man was of unusual intelligence and ability, he was persistent in his denial of any gonorrheal history. He was being treated for suspected prostatic hypertrophy with cystitis, and gonorrhea was not even suspected. In this case gonococci were found on the fourteenth and nineteenth examinations after deep instillations of one percent silver nitrate. In the other patient, there was a clear-cut history of gonorrhea with symptoms, lasting three months, first attack. Here where one would expect to find gonococci, none was found after nineteen tests. Specimens of the morning urethal discharge were likewise negative.

Method of Examination: The object of the examinations being to determine the persistence and tenacity of the gonococci in prostatic secretion, and nothing else, the urethral discharges, if any were present, were examined, but have not been considered in this study. Nor was any attempt made to differentiate between the secretion from the prostate and from the seminal vesicles. These examinations were made at intervals varying from three days to two weeks, and most of them were made in the course of the treatment for chronic gonorrhea. If the urine passed by the patient was clear, this was considered sufficient cleansing of the urethra for the elimination of urethral matter; if the urine was not clear, the urethra and bladder were irrigated without a catheter before massage of the prostate. Of course, this method does not guarantee to the point of scientific accuracy, that there was no urethral contamination, but this risk was shown to be not as great as might be expected. This was made evident in a number of cases with a well-marked urethral discharge which contained gonococci; the massaged secretion from the prostate did not show the presence of gonococci. If contamination were to occur these would have been the cases in which gonococci should have been found in the prostatic specimen. And *vice versa*, in several cases with a morning discharge, which was examined and gonococci not found, the prostatic secretion did show the presence of gonococci.

The examination is facilitated by having the patient stand with his body bent forward, his hands resting on the seat of a chair in front of him. The operator holds a clean slide close to the urinary meatus, with one hand, while the other performs the massage. In this manner, we catch the prostatic fluid as it drops from the urethra. If there is a foreskin, it should, of course, be retracted out of the way. The amount of pressure necessary to bring forth the prostatic fluid varies with the condition of the prostate. If the organ is soft and highly congested, the slightest contact with the finger will often bring forth a gush of fluid that will quickly cover the entire surface of the slide. If the organ is small and hard, quite a good deal of muscular energy is required to get a drop or two on the slide. If the specimen is copious and thick, the excess should be permitted to drain off, and a drop or two of water added for dilution, otherwise the examination will be found unsatisfactory. The fluid is allowed to dry in the air, fixed in alcohol and ether, stained, and examined. If there is no flow from the prostate, the urine passed after massage may be centrifuged and then examined, but this method is not at all satisfactory.

This brings us to the perplexing question, "Does the microscope tell us to a certainty that the germ we see is the real Neisser gonococcus?" In other words, are we justified in regarding the Gram stain as absolutely certain? In this series of cases, the Gram stain was employed, and we have accepted the results obtained by the use of this stain as final and conclusive. There is no doubt that positive culture growths would have been more convincing, but in view of the difficulty inherent in the culture of the gonococcus, and considering the fact that these examinations are the duty of the practising physician or specialist rather than the bacteriologist,

I believe the Gram stain, conscientiously performed, should be accepted as sufficient for our purpose. All the examinations referred to in this paper were made at the Saxe Laboratory and examined and reported personally by Dr. De Santos Saxe, of this city. Dr. Saxe has also presented a paper at this meeting of the Association in which these examinations have been utilized and considered from a somewhat different point of view.

Early in the course of these studies, I found that the instillation of twenty or thirty minims of a one per cent. silver nitrate solution, into the deep urethra a day or two before the prostatic massage, would help to bring forth gonococci that might be hidden in the organ. This was beautifully illustrated in Case 3, Table 2, already referred to and reported at length. In this case after thirteen examinations of the prostatic secretion had been made with negative results, a deep instillation of silver nitrate was given, with the result that gonococci were discovered a few days later. After the effects of the silver had passed away and the reports from the Laboratory were again negative, a second instillation brought the gonococci to the surface for the second time. Since that time I have been alternating the instillations with the prostatic massage. I should also add that after the massage a bladder irrigation of a mild antiseptic was given in every case.

The results of these observations may best be summarized by answering certain questions that suggest themselves:—

(1) Does the presence of clear urine and the absence of clinical symptoms necessarily indicate that there are no gonococci in the prostate? No. Gonococci may not only be found in the prostatic secretion of such a patient, but they may also be found in the clear urine itself Example: Case 13, Table 2. First attack of gonorrhea two years ago, lasted about eighteen months. Four months ago was discharged as cured by the attending physician. Urine clear and sparkling. No discharge or other clinical symptoms. About to marry in two weeks. Came for examination. The morning urine passed by the patient had been examined in the laboratory of Dr. N. Kruskal, a careful observer, and gonococci were found. The prostate was found slightly congested. The secretion was examined and reported by Dr. Saxe to contain "few gonococci, occasional staphylococci, and a moderate number of pus cells." Of four specimens examined two were positive and two negative. Several other cases in this series had clear urine when the gonococci were found in the secretions.

(2) If the first examination is negative as to gonococci, is that to be considered as evidence that they are absent? No. In this series the positive findings were as follows: At the first examination, in three cases; at the second examination, in one case; at the third examination, in three cases; at the fourth examination, in four cases; at the fifth examination, in two cases; at the seventh examination, in one case; at the eighth examination, in one case; at the fourteenth examination, in one case. It will thus be seen that in all the cases except three the gonococci were discovered after the first examination, most of them after the third, fourth and fifth examinations.

Case 16, Table 3, will illustrate this point very nicely: Physician, 38, about to be married. Had his first and only gonorrhea ten years ago. Feels well, except for an occasional morning drop. Urine clear, with a few fine shreds, prostate and vesicles apparently normal. No stricture.

Record of seven examinations:

TABLE 4.

No. of Examination	Gonococci	Staphylococci	Streptococci	Pus Cells
1st	Absent	Absent	Absent	Few.
2d	"	Few.	"	"
3d	"	Moderate number.	"	"
4th	"	Numerous.	"	Numerous.
5th	Small number	"	"	"
6th	Moderate number	Moderate number.	"	"
7th	Absent.	" "	"	Mod. no.

It will be noted that coincident with the appearance of gonococci in the prostatic secretion, there is an increase in the other organisms present, particularly staphylococci; the pus cells are also increased in number. I do not recall a single case in this series in which there was not a secondary infection. I have learned to anticipate the early appearance of gonococci in a patient, whose examinations show a steady increase in the number of other bacterial elements and pus cells. This increase seems to be due to the inflammatory reaction that follows the prostatic massage and the silver nitrate instillations. In one case of this series (case 7, table 2), the appearance of gonococci in the prostatic secretion after the fifth examination was followed a few days later by the development of a rather violent posterior urethritis, which also involved the anterior urethra. Gonococci were very numerous in the urethral discharge. I regarded this case as being simply a reawakening of the old gonorrhea, brought about by artificial stimulation of the latent organisms—this being analogous with the recurrence which follows alcoholic or other excesses in these cases.

This leads us to the next question:

(3) Given a patient without clinical symptoms for a long time and apparently well, is it justifiable to stir up the genital tract in this way, in order to determine the presence or absence of gonococci? Shall we hunt for and dig up any hidden gonococci, or shall we let well enough (or bad enough) alone?

Opinions will differ as to what is best to be done. Some will say, get rid of the gonococci by all means if any are present, for you can never tell when they might awaken and cause trouble. Others, on the other hand, will advise leaving them alone, on the ground that they are not doing any harm, and they might remain quiet for all time. I confess to a feeling that there is virtue in both views. We must recognize the fact that a very large number of men who have had gonorrhea marry in course of time, and do not infect their wives; neither do they suffer from recurrences. If the gonococci persisted in the prostate for years in every case, and remained infectious all that time, after the gonorrhea had passed off, very few married women would escape gonorrheal infection. It is true, and it is a great pity and a crying shame, that a large number of innocent wives are infected by these latent gonococci, but fortunately these are in the minority. A good proportion do escape infection. It is quite possible that the gonococcus loses its virulence after the lapse of a long period of inactivity, and thus becomes innocuous—but how are we to know in any given case that such a happy state of affairs exists? It would seem that the safety of an innocent woman ought to outweigh any fears we might have of stirring up a new infection in an old gonorrheic. The risk of infection is too great to permit any man

to marry in the hope that his gonococci will prove innocuous, and since we are not in a position to say that certain gonococci are infectious and others are not, it is incumbent upon us to point out to those who come to us for advice, that all gonococci are dangerous, and that every possible effort should be made to remove them from any organ in which they might be found. To accomplish this, we should hunt the gonococcus and dig, and dig, and dig until we have found out to our complete satisfaction, whether or not the patient harbors any in his prostate; and if we find any, we should resort to all possible means to get rid of them—irrespective of whatever immediate results may follow. In this way, and in this way only, can we do justice to our patients and maintain a frank and clear conscience as to having done our moral duty to the best of our ability. If, under such circumstances, our patient should marry and his wife should become infected, we shall at least be able to say with truth, that we warned him of the possibility of such infection and took such measures as were within our power to prevent it. More than that we cannot be asked to do.

(4) But how are we to tell that there are no more gonococci in the prostate? These studies are convincing on one point at least, namely, that we cannot tell whether or not any given prostate harbors latent gonococci. Not to find them does not mean that they are not there. The only way in which we can be enlightened is by making repeated examinations with the microscope, or with the culture tube—and if we have made so many with negative results that we feel morally certain that further investigation would be of no avail, we may then, and then only inform our patient that we have gone to the limit of our searching powers and that we feel that further examinations would be useless. We may then declare the patient free to marry, with this reservation, that it is still possible for him to harbor gonococci which might at some future time awaken and resume their activity, and that he should be constantly on guard for the slightest sign of trouble. We should always bear in mind the difference between the patient not having gonococci, and our not finding any, and we should likewise at all times impress this difference on the minds of our patients.

Conclusions: As a result of these investigations, I feel safe in adding the following conclusions to those previously published: (1) A man may be "cured" of his gonorrhea, as far as symptoms are concerned, and his prostate and annexa may contain gonococci; (2) Gonococci may be found in clear urine; (3) gonococci may persist in the prostate for many years, and show no symptoms of any kind; they may not be infectious necessarily; (4) we cannot tell whether or not any given prostate contains gonococci, except by making a large number of examinations of the massaged secretion after stimulation and irritation by silver nitrate, etc.; (5) though it is conceded that cultures are more certain, when successful, than microscopic examinations, the army of practising physicians must rely upon the microscope for their results. Besides, a negative finding in a culture tube is no more enlightening as to the absence of gonococci in the prostate than is a negative finding on a microscopic slide. In either case the thing sought for has merely not been found, which is a different thing from saying that it is not there: (6) the gonococcus should be sought for until every means is exhausted. We cannot be too careful in making our examinations before permitting men to marry. The risk is too great to the innocent wife to consider this matter in any other than the most serious way. If the gonococci are to be stirred up and a possible inflammation aroused by the examinations, it is far better than leaving them alone to be stirred up at some future time after the man has married, and thus have his wife infected.

105 East Nineteenth Street.

A CASE OF MULTIPLE SCLEROSIS.

By CHARLES D. FOX, M.D.,

PHILADELPHIA, PA.

In view of the recently recognized frequency with which multiple sclerosis develops after the occurrence of "idiopathic" retrobulbar optic neuritis the following case, in which this sequence happened, seems worthy of being reported.

When first examined by me the absence of nystagmus, intention tremor, or of any impairment of speech was so misleading that not any doubt was entertained relative to the accuracy of the diagnosis which was made at this time; namely, incomplete transverse myelitis. However, the rapid development of manifestations foreign to transverse myelitis and indicative of multiple sclerosis soon led to the recognition of the true nature of the disease.

Hysteria, which so frequently complicates as well as mimics disseminated sclerosis, made its appearance late. The diagnosis of this complication was based upon the occurrence of transitory, but almost total, paralysis—double hemiplegia: the induction of hypnoidal states by lateral fixation of the eyes; and upon the appearance of an apparently causeless series of syncopal attacks.

Unless the contraction of the visual fields be considered as a stigma there were no other evidences of hysteria, and the patient did not present the usual phenomena dependent upon the hysteric psychic state or temperament.

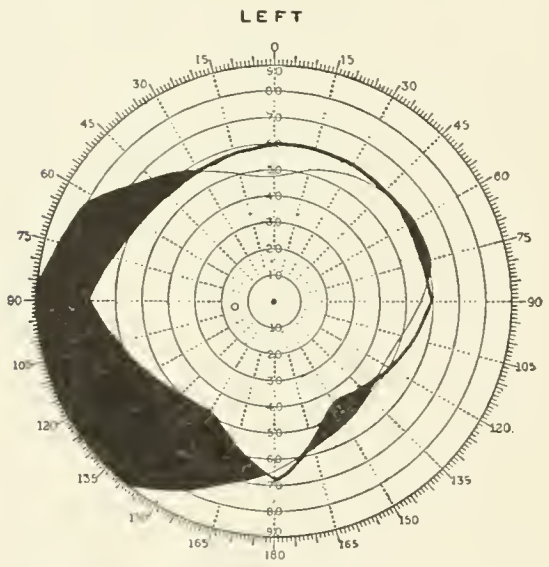
Case.—Mrs. E. S., æt. 29, stated that she was unable to remember ever having ben ill until, in March, 1904, she had "hydrops articuli" of the right knee. An incision was made and she soon recovered from the local condition, but, immediately following, there appeared progressive weakness of the right lower extremity. This weakness rapidly became so severe, during the three weeks which preceded my first examination—June 30, 1906—that she had great difficulty in walking. Furthermore, for several weeks she had been unable to hold her urine for any length of time after becoming aware of the desire to void it, and she was compelled to urinate two or three times each night. The functions of the bowels, however, remained normal; daily movements being habitual.

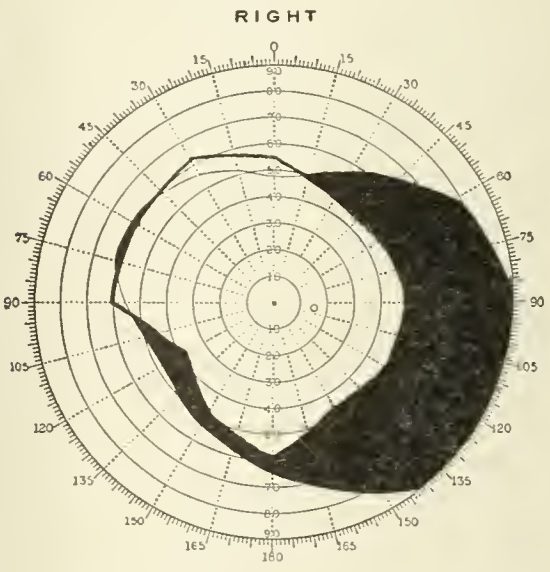
No other symptoms had been remarked by the patient, and, excepting the conditions already mentioned, she considered herself in good health. Headache, tinnitus, vertigo, and diplopia had never been noticed. The menses were regular.

After the true nature of her disease became apparent further questioning elicited the fact that while traveling, in 1905, complete amaurosis developed in the left eye in the course of two or three days; the condition gradually improving so that at the end of several months vision became as acute as it had been formerly.

The following is a translation of a statement, dated May 5, 1905, given to her by Dr. Dufour: "Miss E. G. has been treated for two weeks in the Hôpital Ophtalmique de l'Asile des Aveugles de Lausanne. She presented, in the left eye, a very mild state of optic neuritis. The papilla was a little red and a little diffuse. There was also involvement of the region of the macula. Visual acuity, in the beginning, was about 1/35; there being a relative central scotoma of about 40° in width by 20° in height. The etiology of this affection could not be determined. Her condition when she left the hospital was as follows: Visual acuity, 1/2; there remaining a small central scotoma of about 15° in width by 8° in height. She was treated in a dark room with two applications of leeches; foot baths; sweatings; and potassium iodide internally.'' Her original prescription showed the daily dose of this drug to have been 2/5 of a grain.

Physical examination at the time of her first visit determined the pupils to be equal, normal in size, and reacting well to light, both directly and consensually, and to accommodation. The ocular





muscles functionated well and without any nystagmus of lateral fixation. The visual fields, as examined by the rough finger test, appeared to be normal. There was not any tremor or deviation of the protruded tongue. Both hands were affected with a moderately coarse tremor which did not seem to be of the volitional type and which was not apparent in her writing. The patellar reflexes were greatly exaggerated, the right one being the more so. Typical Babinski's sign was elicited bilaterally with about equal distinctness. The right leg was slightly spastic, but no ankle clonus could be obtained on either side. Muscular force seemed to be unimpaired in both upper extremities, and in the left lower one. There was evident, however, in the whole of the right lower extremity considerable relative reduction of strength. This was most evident in the muscles supplied by the great sciatic nerve and its branches. The circumference of the right calf was ¾ inch less than that of the left leg and the circumference of the right thigh, as compared with that of the left one, was reduced 1½ inches. The tactile, pain, temperature, and muscle senses appeared to be normal. Her gait very closely resembled that of hemiplegia. Coordination was good. The patient, a tall, well built and healthy looking English woman, did not show any evidence of possessing a "nervous temperament."

Her condition gradually improved so that walking no longer necessitated the use of a cane and the hemiplegic gait was barely apparent. During this period of improvement she was delivered of her first child—March 3, 1907—without any difficulty. Severe labor pains were noticed by her for about twenty minutes only, prior to the birth of her child. These severe pains had been preceded, for about twelve hours, by occasional pains which were not severe enough to annoy her. After the termination of pregnancy improvement steadily continued until May 31, 1907, when there occurred sudden and progressive weakness of the right lower extremity, followed by similar involvment of the left one. Examination at this time showed the patellar reflexes to be greatly exaggerated, the right one being noticeably the more increased. Spasticity, besides having developed in the left lower extremity, was more apparent in the right contralateral member than formerly. Typical Babinski's sign was present bilaterally. The tactile, temperature, pain, and muscle senses remained uninvolved. Ankle clonus could not be elicited. The right thigh was one-half inch less in circumference than the left one, the reduction in the former amount of difference being due to the development of slight atrophy of the left lower extremity. Muscular force of both lower extremities was less than formerly; but, with the exception of the muscles moving the foot, the left one was not affected to any extent. The bowels continued to be moved daily in a normal manner and the condition of the bladder functions remained about the same.

Following this aggravation in her condition she progressively improved again until about October 1, 1907, when, upon waking in the morning, she found that she was totally unable to move any part of her body except the cranial muscles. This persisted the entire day and then disappeared. There were not any of the so-called hysteric stigmata present.

About the end of November marked static ataxia

appeared and her other symptoms gradually became intensified. Indubitable intention tremor began to develop in January, 1908, and in the course of a few months became so marked that her writing was almost illegible. The tremor was more severe in the right hand. At about the same time slight hesitation in speech became apparent. Nystagmus was absent. A paretic condition of both external recti and the right internal rectus was noticed only during one examination. The right disc was reported, by Dr. Eaches, to be normal, but the left one seemed pale. The visual acuity was: O.D. 10/15 and O.S. 10/15. Decided amnesia for recent events was made the subject of complaint at this time.

Notes made March 5, 1908, are as follows: Slight cutaneous hyperalgesia with moderate reduction of tactile acuity over both legs and thighs; temperature sense apparently unimpaired; static ataxia sufficient to cause the patient to fall even when the eyes remained open; slight spasticity of the lower extremities with the presence of ankle clonus, both of which signs were more pronounced on the right side; no nystagmus of lateral fixation; visual acuity O.D. 10/15 and O. S. 10/15; visual fields and stereognostic ability normal.

For several weeks following this, she was occasionally unable to speak the word she had in mind and wished to use. This rudimentary aphemia was noticed only in the attempted use of polysyllabic or uncommon words. No other aphasic difficulties were apparent. Staccato speech disappeared about July, 1908.

From April until July spastic paraplegia became severe enough to incapacitate her, but this again became sufficiently ameliorated to enable her, with the assistance of a cane, to walk several squares.

When examined on July 21, 1908, the pupils were equal, normal in size, and reacted well to light and to accommodation. There was bitemporal limitation of the visual fields as determined by the perimeter (see figure). The ocular muscles functionated well but decided nystagmus of lateral fixation was noticed for the first time. The acuity of audition, as tested by a watch, was R. 12/24 and L. 1/24. Galton's whistle showed her upper limit of audibility to be about R. 21,000 and L. 28,000 vibrations per second. Air conduction was better than bone conduction on the right side but bone conduction was superior on the left side. The tongue was protruded in the median line. Decided exaggeration of the patellar reflexes, ankle clonus, Babinski's sign, and spasticity were still present. All of these signs were more marked on the right side. Static ataxia, present to a slight degree when her eyes were open, became severe enough to cause her to fall when she closed her eyes. The gait was typically that found in spastic paraplagia; this abnormality being more apparent on the right side.

During the examination lateral fixation of the eyes caused the production of a state resembling that of hypnosis, or that which accompanies an attack of petit mal. This phenomenon was considered to be the second indication of the coexistence of hysteria. Further confirmation of this belief was afforded on August 11, 1908, when she reported having had twelve attacks of unconsciousness, each of which lasted about two or three minutes and was preceded by an aura of vertigo. Realizing that her organic disease was a grave one and therefore wishing to be at home, she sailed for England several days later.

Before arriving at the diagnosis of multiple sclerosis her medical treatment comprised a course of potassium iodide and mercury; afterwards, phosphide of zinc, silver nitrate, and picrate of zinc were administered at various times. The remissions and aggravations characteristic of disseminated sclerosis would render invalid any conclusions which might be drawn relative to the efficacy of any of these remedies.

In her most recent letter—dated February 16, 1909—the patient stated that, having been constantly under treatment since she had returned to England and her condition remaining unimproved, she had applied for admission to a hospital. The character of her writing was about the same as it had been before she left for home.

2126 Pine Street.

MALFORMATIONS OF THE NASAL SEPTUM.*

By JAMES P. LEWIS, M.D.,

WALTHAM, MASS.

The important part which the nose plays in the comfort and health of mankind is but little appreciated by the laity and not always given enough consideration by those of us whose work lies in other fields. In order that this rôle may be more fully understood it is well to consider the nasal functions from the physiological standpoint for a few moments before passing on to the subject of this paper.

The respiratory function of the nose is of the most importance. The inspiratory air is changed to body temperature, saturated with moisture, and filtered of foreign particles on its way to the air vesicles of the lungs where the exchange of oxygen and carbon dioxide takes place. The turbinated bodies are largely instrumental in producing these changes, their erectile tissue supplying the moisture, while their large surface, by coming in contact with the air, serves to warm it and to catch the finer particles which have escaped the vibrissæ at the nasal orifices. The importance of the normal continuance of these functions can scarcely be overestimated. As the air is warmed it expands and is thereby enabled to take up more water, so that on reaching the lower mucous membrane of the respiratory tract no more can be held, thereby preserving the moisture of these regions. An interference with such processes affects the normal exchange of oxygen and carbon dioxide, diminishing the oxygen and increasing the carbon dioxide, thereby retarding the normal metabolic processes and lowering the resistance by decreasing the activity of the leucocytes. The result is anemia, debility, indigestion, aprosexia, and nervous symptoms of various kinds. Not alone in this manner is the body affected. A blocking of the nose is oftentimes responsible for various conditions giving rise to a retention or hyperaccumulation of secretions in the nasal and pharyngeal regions, which, when swallowed, is the precursor of digestive disorders commonly classed as chronic dyspepsia.

It is to the production of overtones that the spoken and singing voice owes its rich and musical character. These overtones are largely produced in the nasal cavities and sinuses or bone spaces con-

*Read at the monthly meeting of the Waltham Medical Club, November 5, 1908.

necting therewith; it is perfectly evident that anything tending to obstruct these channels will at once affect the quality of the voice.

The olfactory function of the nose is to be regarded as next in importance. The olfactory nerve is distributed over the superior turbinate and corresponding portion of the septum; the air, therefore, must pass over this area to produce an action on the nerve endings, and here again it is evident that an obstruction to this current would render the patient anosmic.

The nose again has a gustatory function which is also presided over by the olfactory nerve, the impairment of which renders our enjoyment of eating less keen, to say the least.

It follows then, that, when we see how important a clear nasal breathway is and of how much value the turbinated bodies are in that breathway, measures to aid the establishment of normal conditions are second to none in importance.

The septum is composed of three parts, an anterior quadrilateral portion composed of cartilage, articulating behind and above with the vertical plate of the ethmoid and behind and below with the vomer. The cartilage is carried backward at the junction of the two bony portions of the septum in a narrow strip, forming what is known as the caudal prolongation, and it is along this portion that spurs are commonly found.

Various theories have been advanced to account for deformities of the septum, of which two have been accepted in the most part. The great majority are probably due to irregular development of the facial bones. Whether the result is brought about by an overdevelopment of the vomer, whereby it requires more room than is present, or whether the want of room is caused by the failure of a high-arched palate to descend, or whether the irregularity is to be regarded as a primary "stigma of degeneracy" accompanying other deformities, is not plain. The delayed eruption of the incisor teeth rendering the hard palate high and narrow and leading to incoordination in its development, is often an important factor.

The second, and undoubtedly true cause in a certain number of cases, is trauma, at times setting up a chronic low-grade type of inflammation; but considering how well the perpendicular plate of the ethmoid is protected by the bridge of the nose and nasal bones, and the great preponderance of such deformities in civilized races, where the chance of injury is comparatively slight, that it can account for a large percentage of cases is unlikely.

Malformations may be classified as spurs or ridges, thickenings or deviations, either of which may exist alone or in combination and may be cartilaginous or bony. They vary in their importance according to the amount and character of the obstruction which they cause, interference with the drainage and ventilation of the sinuses by encroachment on the middle and superior meatuses being the most serious. Spurs and ridges usually take the form of crests, spines, or rounded thickenings confined to the cartilaginous septum, though sometimes they may become partially ossified. A somewhat common spur occurs on the bony septum, starting just behind the quadrilateral cartilage. It follows the junction of the perpendicular plate of the ethmoid with the vomer and runs in an upward and backward direction, projecting more and more from the septum as it proceeds. Such an one is usually osseous. A very important type of deviation is that in which the perpendicular plate of the ethmoid becomes bowed, impinging upon the middle turbinal, for this obstructs both the drainage and ventilation of the frontal, ethmoidal, and sphenoidal cells. This type is also frequently accompanied by the ridge along the crest of the vomer, usually on the opposite side, so that the septum has an S-shaped appearance. The so-called dislocation of the quadrilateral cartilage where its anterior extremity is turned to one side, is also fairly common.

While many septal deformities exist with no symptoms and are not detrimental to the health, they are often the cause of severe local and general complications, in which case they are obstructive or irritative in character. The symptoms most generally met with are: (1) a sense of stuffiness in the nose, low down when the inferior turbinal bone is pressed upon, higher up over the bridge when the middle turbinate is affected. (2) Pain is frequently complained of, the frontal region, bridge of the nose, and inner angle of the orbit being the usual seats. Pain on pressure over the latter region is very significant of anterior ethmoidal inflammation, while frontal headache is often found associated with high deviations and is present on awakening in the morning, differing from that due to ocular trouble. (3) Irritation of the ethmoidal and frontal sinuses is sometimes accompanied by dizziness, which is brought on or increased by sudden movements of the head and jarring of the body, and is present when the eyes are closed, which serves to differentiate it from that of ocular origin. (4) Asthma is sometimes due to irritation caused by the deformity. (5) An increased nasal secretion is usually present, the secretion being thick and mucoid in character when the mucous membrane is inflamed low down, or sometimes thin and acrid and may become purulent when the sinuses are affected. (6) Postnasal catarrhal inflammation is present when the nasal obstruction prevents the drainage of the secretions and they flow back to the epipharynx. (7) When the obstruction is well forward or low down nasal respiration is usually obstructed. The descent of the diaphragm during inspiration creates a lessened pressure in the nasal chamber which offers the obstruction to the air, thereby drawing the blood of the turbinates to the surface and rendering them turgid and obstructive. The amount of obstruction will vary from time to time, but its secondary symptoms persist, as dry pharyngitis, laryngitis, and tracheitis, disturbed sleep, nasal voice, and mental sluggishness. Besides the appearance of the septum itself, some of the more common objective symptoms are (1) external deformity of the nose: (2) epistaxis, due to the formation and separation of crusts which collect where the dust-laden air impinges on the prominent part of the deformity; (3) the presence of pus in the olfactory fissure between the deviated septum and middle turbinate, and (4) simple dry rhinitis on the unobstructed side.

The more important diseases which may be caused or aided in their development by septal deformities are all of the inflammatory conditions of the nasal mucous membrane, acute and chronic inflammation of the sinuses, acute and chronic otitis media, chronic catarrh of pharynx and larynx, trachea, or bronchi, nasal neuroses and polypoid degeneration of the nasal mucosa. In practice we find that various obscure symptoms may disappear following the restoration to normal of the nasal passages.

The early operations for septal deviations were various types of cutting and crushing procedures in which destruction of the resiliency of the septum was made, thus allowing the obstructive parts to be pushed to the other side. These are often advisable at the present time, on account of the simple technique and lessened shock to the patient, and are preferable to the employment of the more recent submucous resection. The following are among the best known and most effective:

The Watson operation consists in making an L-shaped incision through the septum and pushing the deviated portion to the other side and is adapted to angular cartilaginous deviations.

Sluder's operation is available only for marked angular deviations. Three incisions are made parallel with the crest of the projection. These are carried through the cartilage, leaving two strips attached in front and behind only, which, when forced into position, overlap.

The Gleason operation consists in the formation of a U-shaped flap, having its base upward, which includes the cup-shaped deviation, the one in which this method is applicable. The flap is then forced to the open side, its resiliency being overcome by fracturing its base.

In the Asch operation a crucial incision through the septum is effected by means of special instruments, forming four triangular flaps, which are forced to the open side and held with splints. It also is employed in cup-shaped deviations.

The Roe operation is performed by using a specially made forceps having a male and female blade. These are adjusted over the septum, the male blade on the side of the convexity. On closing the blades the projecting portion of the septum is forced to the other side, being fractured in the process. This operation may be used in any case not exhibiting a heavy ridge.

In the Kyle operation a long V-shaped portion of the septum is removed along the line of greatest convexity. The incisions are made with a special saw and are not carried entirely through the septum, which is afterwards straightened and held in position with nasal splints.

The Price-Brown operation consists in making two parallel incisions and uniting them by another as in the letter H. The flaps thus formed are then pushed to the side of the concavity.

Simple spurs and ridges may be removed with the saw, spokeshave or chisel, while soft septal hypertrophies may be reduced by application of the actual cautery.

Recently the submucous resection operation has largely superseded all others, as it may be applied to any deviation, and when successful its results are usually superior to those obtained in other ways. This consists essentially in the elevation of the perichondrium and periosteum on both sides of the septum, to include the deformity. This is done through a vertical anterior incision, usually on the obstructed side, as practised by Hajek or Killian, which may be supplemented by an anteroposterior incision according to Freer, if occasion arises. The obstructive portions of the cartilage and bone are then removed without injury to the mucous membrane and the flaps allowed to fall into apposition, being held by suitable packing for 24°-48°, healing taking place by first intention.

Various instruments have been devised to facilitate these different steps, the choice of which depends upon the individual operator. It is probable that the cartilage does not reform, its place being taken by fibrous connective tissue. The gland elements, however, are but little changed.

The advantages of this operation are its applicability to all forms of obstruction, its excellent result and the comfort to the patient from the absence of nasal splints and short convalescence.

Its disadvantages are the difficulty in performing the operation, thus increasing its length with corresponding shock to the patient and making its results a little more problematical than with a simpler method. Irritation due to vibration of the membranous septum in the air-stream is sometimes noted.

As its chief disadvantages may in considerable measure be controlled by the operator, it seems probable that they will continue to be less prominent as improved technique is developed.

55 Grant Street.

REMARKS ON FLAT FEET.

By MAX STRUNSKY, M.D.,

NEW YORK,

ASSISTANT SURGEON IN THE HOSPITAL FOR DEFORMITIES AND JOINT DISEASES, NEW YORK; FORMERLY ADJUNCT TO THE CHAIR OF ORTHOPEDICS IN THE COLLEGE OF PHYSICIANS AND SURGEONS, SAN FRANCISCO, CALIFORNIA.

The muscles which hold the arch are chiefly the tibialis posticus and anticus. Their tonicity is diminished or often destroyed by inflammation, interference with metabolism or over-fatigue, due to standing, paresis, or paralysis of the nerves supplying this group. The diminished tonicity relaxes the contractile element and causes an actual lengthening of these muscles. The superincumbent weight then falls directly upon the foot, which stretches the tarsal ligaments and displaces the tarsal bones. The tonicity of these muscles is highly susceptible to toxins, as shown by the frequency with which patients develop flat feet who are convalescing from attacks of contagious diseases. Also there is a high percentage of flat feet in patients who are suffering from wasting diseases. This certainly could not be explained by the theory of mere coincidence, but rather by the decrease of tone of the tibial muscles, due to toxins in the blood, or disturbed metabolism which always exists in serious diseases.

Fig. 1.—Imprint of flat feet, patient standing

Occasionally a patient comes to us with the sole complaint of pain in the feet and flat arches. Examination, however, reveals an Argyll-Robertson pupil and other symptoms of locomotor ataxia. Sometimes a patient whom we treat for flat feet does not live up to our favorable prognosis. When by accident or intention we examine the urine we may find there sugar or evidence of nephritis, which explains the retarded progress. Was there ever an orthopedist who did not have the unpleasant experience of treating a case of supposed flat foot and finding the patient getting worse instead of better until it dawned upon him that the clammy foot with subjective pain very much out of proportion to the deformity was not at all a case of flat foot, but arteritis obliterans, the bane of foot practice?

When the arches are flat, the diagnosis is flat feet. The crucial test of the strength of the arch is not their appearance when the weight of the patient is off his feet, but rather when the weight is upon them. This we can only ascertain by the mirror test or by careful and scientific imprints. It often happens that patients have normal arches when they are in the sitting or lying position, but as soon as they stand up their arches become completely flat. I beg to submit imprints of a case which illustrate this point (Fig. 2).

Fig. 2.—Imprint of normal feet, often seen in flat feet when the patient sits.

The lesion of flat feet is a dislocation of tarsal bones which does not differ in any respect from dislocation of bone anywhere else in the body, with the exception that the process is less acute. The bones that are chiefly affected in this deformity are the astragalus, which is pushed downward, forward, and inward, and the scaphoid, which becomes rotated. The pain in flat feet, as in dislocation, is due to the pressure of displaced bones on nerves and tissues, to the stretching of ligaments and to reactive inflammation. In chronic cases adhesions, ankylosis, and spasms of muscles add to the suffering. Early reduction is followed by the disappearance of symptoms and the restoration of normal anatomical relationship and function of the joints. If unreduced it usually remains a joint with chronic inflammatory symptoms, adhesion, ankylosis, limited motion of joints, deformity, and abolition of function.

The prophylaxis is difficult and often impossible to enforce, for the reason that among the important causes of flat feet is the abuse of the feet by too long standing, bad shoes, and false position in walking. Too long standing is often impossible to rectify, because the majority of these patients are laborers whose occupations require it. The false position in walking, viz., with heels in and toes out, was so long taught in the armies and schools that it has become instinctive in civilized races. This position shifts the line of weight which normally falls on the middle and strongest part of the foot to the inner border. Most modern shoes are made pointed. Physiological walking requires the toes to remain spread, with plenty of room to execute a prehensile movement. The modern shoe squeezes the broad, fan-shaped portion of the foot and converts it into an apex. The majority of patients who come to us for the relief of flat feet bear evidence of this shoe-abuse in corns, bunions, hallus valgus, and other deformities of the toes, which are responsible for the breakdown of the arch.

The best treatment in the acute inflammatory stage is physiological rest, with the patient in bed. This, however, is often impossible, and we resort to the substitute of strapping the arch with adhesive plaster or supporting it with felt, or, best of all, with thin celluloid plates. Professor Schantz of Dresden uses hot, effervescing foot-baths with good results, as well as support. In the subacute stage massage is added.

Fig. 3.—Celluloid plate for use in flat feet; side view.

The metallic plates often give rise to pressure-symptoms while the celluloid plates, on account of their resiliency, seldom do. In the last fourteen months I have made 125 pair of celluloid plates according to the method of Professor Schantz. In comfort, lightness, and cleanliness, celluloid plates are ideal. When the inflammatory symptoms have subsided, in addition to support, gymnastics should be commenced. I cannot speak too highly of the value of gymnastics in the treatment of the chronic stage, as it is the only means we have which strengthens the muscles, breaks up tarsal adhesions, develops the elasticity of the joints, and increases the range of adduction. When ankylosis has already set in, patients should still be given the benefit of a course of active and passive resistance exercises before resorting to "brisement forcé."

95 West One Hundred and Niniteenth Street.

CONSERVATISM IN THE USE OF FLAT-FOOT PLATES.

By ROLAND O. MEISENBACH, M.D.,

BUFFALO, N. Y.

CLINICAL INSTRUCTOR IN ORTHOPEDICS, UNIVERSITY OF BUFFALO.

The foot is normally a springy mechanism which is governed by the action of the leg muscles. The tone of these muscles varies in different individuals and often depends upon the amount of work which is thrown upon them. Thus, in a heavy person, much more work is required than in a person of lighter weight. Also, in an individual with a general debilitating diathesis, the tone of these muscles may be below par and not strong enough to keep the springy mechanism in the normal attitude. It is frequently noted that individuals have a right and

left foot entirely different in muscular development and tone, and consequently different in functions also.

There are very few normal feet among the civilized shoe-wearing peoples. This fact is probably due to the muscular atrophy which shoes bring about, together with the joint strain which is caused by the mode of dress, especially among women, whereby the balance of the body is thrown in such a way as to overtax the mechanism of the foot and to break the equilibrium of the muscular action about the ankle joint.

For the correction of the static foot error in posterior flat-foot, flat-foot plates are frequently essential in some stage of the treatment. The objects of flat-foot plates are: (1) to guide the muscular action and thereby assist in restoring the tone; (2) to restore the general balance of the destroyed muscular equilibrium and allow the muscles, tendons, and ligaments to contract; (3) after the muscular equilibrium has been established, to prevent the recurrence of the asymmetry of muscular pull and thereby establish a functionating foot which eventually will become strong enough to do its own work without the assistance of plates.

In order to accomplish the above, it is necessary to prepare the foot for the wearing of plates in some instances, which is done by active and passive force applied either with or without an anesthetic. When the foot is flexible and no complications are present, the slow process of building up by means of felt pads is the most satisfactory. If the diagnosis of the foot condition warrants the immediate application of plates, these should be made of average height and gradually raised at intervals of from three to six weeks until the foot assumes its normal muscular action, but by no means should they be rigid so as to restrict muscular action.

The material for the plates should be sheet steel, gauging from 22 to 16, according to the weight of the patient, and the surgeon's desire to bring certain groups of muscles into play. The author has tried many materials, and finds that heavy bronze, German silver, copper, brass, white metal, and sole leather are unfit for flat-foot plates because they do not allow enough spring and have a tendency to weaken all muscular and ligamentous tone about the foot. Plates made of these materials are frequently much more easily worn by the patient, who is not aware of the harm that is being done, and who finally becomes dependent upon them. The author has seen much harm done to the feet by plates of this kind.

The technique for the preparation of the steel plates, in brief, is as follows: The casts are made of the feet in the usual manner. These casts are then cut by the orthopedic surgeon according to the symptoms of the patient, and the gauge is prescribed according to the amount of work he wishes the plate to do. These plates are then fitted to the patient and changed in height or shape, as the individual foot may require. They are then tempered, and covered with a thin coat of celluloid, leather, or nickel, as one may choose. In some cases the plates should not be finished and the patient should be allowed to wear the tempered plates for a week or ten days, so that alterations may be made, if necessary. Often, at this time, the plates can be safely raised to a greater height.

The practice of placing the patient upon any "arch-support," as is the custom of many physicians, is decidedly harmful to the patient in more than one way. In the first place, in nine out of ten cases, there is no diagnosis of the foot condition made. The patient is placed upon any support and receives temporary relief, but in a short time he is worse off than before. This fact has been called to my attention so frequently that there is no question, in my mind, but that it is as important to fit a patient with proper plates as it is to fit him with proper glasses. The use of the steel supports requires more skill on the part of the orthopedist, and is harder for the patient in some stages of the treatment, but the ultimate results are unquestioned—an improved functional foot with the prospect of an early removal of the plate, entirely or partially. In some cases the plate is prescribed only when the feet become fatigued.

In order to accomplish the best results in flat-foot work with patients who require plates, exercises should be given in conjunction with the wearing of plates. These exercises should be changed from time to time as there is improvement, or if no improvement occurs. This is especially true with children who are growing rapidly. The foot exercises should be continued for a considerable period after the patient has ceased to wear the plates, with the view of conserving the good that has been gained by the use of the plates.

The object of these notes is to emphasize the harm that may be done by the promiscuous use of flat-foot plates when applied by persons without skill and knowledge acquired by conscientious orthopedic training.

140 Allen Street.

Indications for Cesarean Section in Prolapse of the Cord with Contracted Pelvis.—A. Couvelaire, having examined the statistics of prolapse of the cord combined with contracted pelvis found at the Hôpital Baudelocque, between the years 1893 and 1904, gives the conclusions at which he arrives. When the prolapse is irreducible, no matter what is the disproportion of the head to the pelvis, there is an indication for the cesarean section, because the life of the child may be sacrificed. When it is possible to reduce the cord and remove it from compression, if there is not great disproportion between the head and the pelvis, section is not indicated. But with great disproportion it is better to perform cesarean section than to rely upon symphyseotomy, after dilatation has become complete. Compression of the cord may occur at any time and dilatation may be very slow, so sacrificing the life of the child. Operative interference should not be deferred.—*Annales de Gynécologie et d'Obstetriques.*

Biliary Ileus.—Leriche and G. Cotte say that biliary ileus is caused by cholecystitic adhesions of the peritoneum by a large gall-bladder full of stones which press upon the intestine, by paretic phenomena consecutive to peritonitis, and, more frequently, by an abnormal migration and arrest of a calculus in the lumen of the intestine. This complication is relatively frequent, is more common in women than in men, and occurs after the age of forty years. It is generally produced by a single calculus which has found its way into the intestine by ulceration from the gall-bladder without passing down the ducts. It occurs most frequently in the lower part of the small intestine. The calculus becomes coated by fecal matter which enlarges its size. The most common added factors in its production are cicatricial stenosis, tuberculosis, neoplasms, and adhesions. Ulceration may cause spasm of the intestine. The wall of the intestine becomes inflamed and ulcerated and peritonitis may set in. In general obstruction comes on suddenly, since it is only with large calculi contained in the gall-bladder that the intestine can be obstructed. In obstruction high up in the intestine grave symptoms occur early. The obstruction may last for 6 to 10 days and then the calculus appears in the stools. Symptoms may disappear for a time to reappear in crises. In many cases spontaneous cure occurs. Obstruction situated high up is almost always rapidly fatal. A medium laparotomy is the best operation, followed by incision at a little distance from the obstruction and the removal of the calculus.—*Gazette des Hôpitaux.*

POSTERIOR BASIC MENINGITIS.

THERE has been for a number of years a certain mystery connected with the name posterior basic meningitis, an uncertainty as to the exact nature of the disease, and a difficulty in determining its proper position in the classification of the meningitides. Described first by Barlow and Gee, and later studied by Barlow and Lees, it was considered for some years to be a definite clinical entity, an opinion which from the symptom complex and pathological picture seemed to be thoroughly justified. The age incidence, it practically always occurring in infants of less than one year old, and often in those under six months, the extremely marked opisthotonus, the so-called "post-basic stare" produced by the retraction of the upper lid with the rolling downward of the eyeball, and the tendency to recover, served to differentiate the disease from tuberculous meningitis. On the other hand, the fact that it was rarely fatal before the third or fourth week and often not for many months, and that it ran practically a nonfebrile course were sufficiently characteristic to differentiate it from the more common cases of epidemic meningitis or spotted fever, and from the other purulent meningitides. The peculiar localization, too, of the thick pus to the posterior portion of the base of the brain seemed to be typical of this disease alone.

The first serious doubts of the independence of posterior basic meningitis were cast by Still in 1898, when he isolated from the meninges of eight typical cases organisms which he was unable to distinguish from the *Diplococcus intracellularis meningitidis* of Weichselbaum, the etiological factor in epidemic cerebrospinal meningitis. Since that date, particularly in England, where most of the work on this disease has been carried on, the belief in the entity of posterior basic meningitis, though dying hard, had gradually waned, and the opinion has become steadily more common that the condition is not a disease in itself, but a manifestation of a chronic type of cerebrospinal fever occurring, not during epidemics, but either after or entirely independent of them.

Two years ago the subject was again brought up by Houston of London, who compared the organisms of this disease with some obtained from the epidemic of cerebrospinal meningitis in Belfast, and stated that, while culturally similar, there was a total lack of agglutination and opsonin reaction of the organisms of posterior basic meningitis with the serum from an epidemic case, and *vice versa*. Recently in this country Martha Wollstein of the Rockefeller Institute has obtained from Houston three cultures of diplococci from posterior basic cases, and compared them with fourteen strains of the epidemic variety taken from Flexner's collection and from fresh cases. Her results, which are reported in the *Journal of Experimental Medicine* for July, 1909, show that, while she had but limited opportunity to obtain serum from fresh human cases of meningitis for her investigations, by using immune horse serum she was able to demonstrate no difference between the reaction of the two classes of organisms, and she believed that the Flexner-Jobling serum should be of value in the treatment of posterior basic meningitis.

This difference in the findings of the two bacteriologists is most unfortunate, as it puts the subject back into much the same state of uncertainty in which it was a few years ago. The opportunities for proper study and comparison of these two diseases have been poor, for whereas the posterior basic variety has been relatively common in London for many years—our knowledge of it, in fact, being a product of the Great Ormond Street Children's Hospital—the epidemic disease has until quite recently been very rare there, and, on the other hand, while in this country cerebrospinal fever has, at least in New York City, been a tragically familiar sight, typical cases of posterior basic meningitis are scarce indeed. Few observers have, therefore, had the opportunity of studying the two diseases together. There can be no question that the two conditions are closely allied, but the bacteriologist will have some difficulty in persuading the clinician that they are the same disease. Three years ago, before the recent epidemic in England, when sporadic cases of cerebrospinal meningitis were almost unknown in London, there was rarely a day on which one or more posterior basic cases could not be found in the wards of any of the great children's hospitals of that city. If the organisms of posterior basic meningitis are identical with those of epidemic cerebrospinal meningitis, those prevalent in London at that time and producing the slow chronic nonfebrile posterior basic meningitis were remarkably uniform in their behavior and must have been in a very attenuated state as compared to the virulent micrococci which caused the acute, rapidly fatal disease which has recently caused such havoc in New York, Belfast, and Edinburgh. Further investigation is required in a locality where the two diseases can be observed side by side, fresh cultures made, and plenty of human serum obtained for agglutination and opsonin reactions. In the meantime, until the matter is settled, every case of posterior basic meningitis may well be treated with the Flexner-Jobling antimeningococcus serum. Besides giving the infant the chance for recovery offered by the serum, such a procedure might add valuable information as a therapeutic test of the unity of the two diseases.

EPILEPSY AND EPILEPTOID CONDITIONS IN CHILDHOOD.

It has long been a mooted question as to what extent convulsive manifestations during infancy and childhood are an expression of true epilepsy or not. A comprehensive discussion of this subject has been furnished by G. Aschaffenburg (*Archiv f. Kinderheilkunde*, Vol. 46, p. 242), who accepts the classification of infantile convulsions made nearly ten years ago by Hochsinger. The latter divided all the convulsive phenomena of childhood into two groups, the first including the simple variety and the myotonia of the newborn, while the second group comprises those convulsions that are due to hyperexcitability of the nervous system. In the former group laryngeal spasm never occurs, and the convulsive outbreaks may usually be traced back to some infectious fever, autointoxication, etc. In the second group, which comprises the condition widely recognized by German pediatrists as pathological spasmophilia, the convulsions are again classified into four different categories, as follows: 1. Respiratory spasms, occurring as an initial or accompanying phenomenon of clonic convulsions of the extremities associated with loss of consciousness; 2. Eclampsia, associated with laryngeal spasm, occurring either before, during, or after the convulsion; 3, genuine tetany; and, 4, nodding spasms. The author believes that infantile epilepsy includes all those cases occurring early in life that do not belong to any of the above groups. He asserts that the usual conception of epilepsy is too narrow. It may be broadly defined as consisting of periodic disturbances of the psychic equilibrium, producing mild or severe disturbances of consciousness, with or without convulsions. The latter are not a necessary factor in the clinical picture. As attacks of true epilepsy he characterizes the outbursts of distemper in children, which are periodic in their occurrence, and which frequently attain the height of true maniacal outbreaks. It had been noted by Pfister that the hereditary victims of epilepsy and hysteroepilepsy, even before the outbreak of the typical, periodic, epileptic convulsions, and beginning during the fourth year of life, exhibited such outbreaks of distemper, sulkiness, and an indisposition to play, which seizures appeared to be the first manifestations of the epileptic condition. It is, therefore, not a matter of indifference that an early diagnosis of epilepsy should be made from such a clinical picture, however much it varies from our usual conception of the disease. Of greater importance, however, is the fact that by means of a rational prophylaxis it is possible to retard the further development of the disease. It is not punishment, but rest and bromides that these children need. The author of this paper does not doubt that the term epilepsy is a generic one, and includes a number of diverse forms, whose mutual relationships are not as yet known. He is inclined to recognize a possible connection between infantile spasmophilia and epilepsy, although he admits that such relationship cannot be proved.

Against this view may be cited the observations made by Walter Birk (*Muenchener Klinik*, 1907, p. 318), and by the same author in conjunction with M. Thiemich (*Jahrbuch f. Kinderheilkunde*, Vol. 65, 3d Series 15, No. 1), on the later development of 53 eclamptic infants studied in the pediatric service at Breslau. None of these children later became epileptic, but only one-third showed normal development, the remainder showing some form of cerebral degeneration. Of those that attained the school age, only one-half progressed normally, while the remainder were sent to schools for defectives. It is noted that one-quarter of the children attending the latter gave a history of spasmophilia during infancy. Even in those children whose mental development was apparently normal, there was observed an increased sensibility and a nervous voice, while light sleep, pavor nocturnus, headache, anorexia, and morning vomiting were common occurrences.

REINFECTION IN SYPHILIS.

One of the most disputed points in the pathology of syphilis has been the question of immunity derived from a single luetic infection. Ricord formulated the law of permanent immunity after a single infection, and later Fournier added the great weight of his knowledge and authority to this view of the matter. Little by little, however, reports of a second infection in syphilitics began to appear in the medical press, and in a recent monograph on the subject published in Volkmann's "Sammlung klinischer Vorträge," Felix John has succeeded in collecting three hundred and fifty-six such reports. Of course, to an implacable believer in perfect immunity as a consequence of a single luetic infection all such data are irrelevant because such a man is always ready to attribute any manifestations of the disease to the first infection, however improbable such an explanation may be. To the unbiased, however, John's monograph is certainly convincing in establishing the fact that a single luetic infection, while it makes a second attack of the disease unlikely, does not render it impossible.

John has applied most exacting criteria in judging the reports gathered by him, and finds that fourteen instances at least meet every possible objection. The first infection in these cases was diagnosed by competent syphilologists; secondary and tertiary manifestations of the disease followed in due course; many years later another lesion was acquired after an exposure to infection, and again the affection ran its usual, though somewhat milder, clinical and pathological course. Sixteen other cases, just as convincing so far as internal evidence of the occurrence of a second infection is concerned, suffer simply from incompleteness of the printed report or the shortness of the period of observation. Many other cases reported serve as corroborative evidence of the possibility of reinfection with syphilis, though the great majority of the reports found in literature cannot be accepted as instances of such occurrence. Anyone, however, familiar with the frequently fallacious conclusions appearing in the current medical reports will grant that such a percentage of unacceptable evidence is not unusual in any disputed question.

The discovery of the *Treponema pallidum* has, of course, brought with it the possibility of more direct and conclusive proof of the occurrence of reinfection with syphilis. Indeed, one or two of the instances quoted by John occurred recently enough to have allowed the demonstration of this organism in some one or another stage of the disease. The total evidence brought forward by the author is, however, such that any new and more complete reports can only make assurance doubly sure, for his interesting work shows sufficiently well that reinfection in syphilis is as possible as in any other disease that confers some immunity upon the patient. Such immunity, however strong, is quite probably never absolute so far as all possible cases are concerned.

The Precancerous State.

In the absence of precise knowledge of the etiology of cancer all attempts at prophylaxis must be gropings in the dark. At the same time it has seemed that certain kinds of benignant growths are more apt than others to degenerate into cancerous growths, and that certain kinds of irritation predispose to the occurrence of cancer. The avoidance of such irritations and the successful treatment of such growths are two steps in this difficult problem of prevention. O. Laurent, writing in the *Revue Médico-Sociale* for May, 1909, has developed this idea of prevention. If chronic irritation of any nature may be regarded as the antecedent of cancer, if certain processes become more often than others cancerous, factors that incite to malignancy, preparers of an appropriate soil for cancerous growths, these may be avoided. Among these states he denominates inflammatory hyperplasia, functional hyperplasia, and heterotypical growths. Examples of this are nævus pigmentosus, papilloma, and adenoma; chronic gastritis and ulceration of the stomach; deep cervical fissures and various other scars; biliary calculi, and goiter. Melanotic epithelioma develops always at the expense of nævus pigmentosus, and leucoplakia is often precancerous. The careful treatment and removal of such lesions becomes a medical and surgical duty of the practitioner. Embryonic heterotypical conditions, chronic inflammatory growths, and metatypical tissues are always to be regarded as bad things at once to be gotten rid of.

The Thaw Decision.

The decision of Justice Mills that Thaw, the murderer of Stanford White, is a paranoiac, and as such unfit for freedom, is one that cannot fail to give satisfaction to all sane citizens. It was preposterous that a dangerous lunatic should be loosed on the testimony of laborers, ministers, and other ignorant laymen who had met him casually and held a few moments' conversation with him on indifferent subjects; yet a judge of less judicial mind than the one who rendered the decision might conceivably have been led to share the delusion of the man's afflicted mother that there is a conspiracy to keep him behind the bars of an asylum if not a jail. In his admirable review of the evidence in the case, Justice Mills lets it be seen that the testimony of Dr. Baker of Matteawan had much to do with the final decision to dismiss the writ. This is another ground for satisfaction, as showing how murder trials and proceedings of the kind just closed would be conducted if the medical experts were public officers, hired and paid by the State, absolutely free from bias, and without the temptation to testify in a way pleasing to the side from which came their fee. The charge of venality so freely made against the medical profession in general and medical expert witnesses in particular during the first and second Thaw trials, could then no longer be made. If, as a result of this trial, the needed reform in the matter of expert testimony is accelerated, the patient at Matteawan will, albeit unwittingly, have rendered one real service to the community.

Mr. Edward T. Boag.

All graduates of the College of Physicians and Surgeons of New York City will learn with sorrow of the sudden death of Mr. E. T. Boag, late registrar of the College. He was drowned in Raquette Lake in the Adirondacks on Tuesday, following the upsetting of a canoe. Mr. Boag was seventy years of age and had been registrar of the College for forty years, until June of this year, when he retired. He was thus known personally to many generations of students, and will be remembered with esteem and affection by the great majority of the living graduates of the school.

News of the Week.

New York Academy of Medicine.—The Wesley M. Carpenter Lecture for 1909 will be delivered on Thursday, October 21, at 8.30 P.M., by Dr. H. T. Ricketts, Professor of Pathology in the University of Chicago. Subject: "Some Aspects of Rocky Mountain Spotted (Tick) Fever, as Shown by Recent Investigations." The anniversary address, November 18, will be made by Dr. Louis Livingston Seaman, late Major and Surgeon U. S. Engineer Corps. Subject: "Personal Observations on the Sleeping Sickness in Central Africa."

Examination for the Indian Service.—The United States Civil Service Commission announces an examination on September 8, 1909, to secure eligibles from which to make certification to fill two vacancies in the position of physician (male) in the Indian Service at Nett Lake, Minn., and Volcan, Cal., at $1,000 per annum, and other similar vacancies as they may occur in the Indian Service. The examination will consist of the following subjects: Letter-writing, anatomy and physiology, chemistry, materia medica and therapeutics, surgery and surgical pathology, general pathology and practice, bacteriology and hygiene, and obstetrics and gynecology. The age limit is 25 to 55 years on the date of the examination. Men only will be admitted to this examination. In accordance with a recent act of Congress an applicant for this examination will be required to be examined in the State or Territory in which he resides and to show in his application that he has been actually domiciled in such State or Territory for at least one years previous to the examination. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application form 1312. No application will be accepted unless properly executed, including medical certificate, and filed with the Commission at Washington.

Inadequate Vital Statistics.—The extent to which the United States is behind other nations in

the matter of completeness of birth and death statistics has been shown recently by the following statement from Census Director Durand: "The States having effective registration laws of death are as follows: California, Colorada, Connecticut, Indiana, Maine, Maryland, Massachusetts, Michigan, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, South Dakota, Vermont, Washington, and Wisconsin. Minnesota, Montana, Nebraska, North Dakota, Ohio, and Utah have recently adopted laws whose results are now under observation. Other States have registration laws which do not meet the requirement of this office. The vital statistics reports of the bureau relate solely to deaths, no State nor even a single city being yet certainly known to have a complete registration of births (90 per cent. of all births that occur—minimum standard) to warrant its admission to the registration area for births."

The New York Osteopathic Society has started proceedings before the Supreme Court in Brooklyn to obtain an injunction restraining the New York Board of Health from enforcing the new section of the Sanitary Code which requires that death certificates must be signed by those having a degree of doctor of medicine and makes no provisions for other registered practitioners.

School for Consumptives in Chicago.—There was recently opened in Chicago by the Board of Education a special school for tuberculous children on the grounds of the Harvard School, Seventy-fifth street and Vincennes avenue. The school is held out of doors in tents. The Board of Education supplies tents, grounds, equipment, and teaching force, while the Chicago Tuberculosis Institute furnishes food, transportation, and medical services. The school opened with thirty pupils selected from a large group of so-called "physically subnormal children," after a careful examination to determine those best fitted to make the experiment.

The National Red Cross Society is planning to increase its membership from 20,000 to 100,000. In a letter recently published President Taft heartily endorsed the proposed increase in the society.

The Governor of New Jersey on Medical Experts.—At a recent address to the surgeons of the the National Guard at Sea Girt, Governor Fort took occasion to express his opinion of expert medical witnesses in homicide cases. He said, regarding them: "During my term upon the bench of the Supreme Court of the State it was my privilege to see much of the medical men of the State. Experience has given me great faith in the medical witness—not, however, the medical expert witness, so-called. My faith in this latter class has never been great, and observation has only tended to lessen my opinion of him. Courts and juries give great weight to the testimony of the local medical practitioner, but very little to the man who appears as an expert witness, especially in homicide cases. The man who testifies to-day in a homicide case that the defendant is insane and then shortly afterward testifies that he is sane is neither influential with the courts nor respected by them. He is an injury to the profession and to the cause of justice."

Recovery Among the Criminal Insane.—Dr. Lamb, medical superintendent of the Matteawan Hospital, in a recent report states that of thirty-four persons released from the hospital as supposedly cured, "fourteen returned to the hospital or prison; eight became partially insane again, two killed themselves, three became dependent upon relatives, six disappeared, and one was in part self-sustaining."

A New Health Board Building.—The New York Board of Health has sent a communication to the Board of Estimate stating that the building now occupied by the Department at Fifty-fifth street and Sixth avenue is too small for its needs, and asking authority to purchase a building now in course of erection at Irving place and Sixteenth street. The desired building is twelve stories high and covers a plot of ground 100 by 123 feet; it can be bought for $850,000.

The Army Nurse Corps.—Miss Jane A. Delano of New York has been appointed superintendent of the Army Nurse Corps, *vice* Miss D. H. Kinney, who resigned several weeks ago. Miss Delano was formerly superintendent of nurses at the Bellevue Hospital in New York City and is president of the National Association of Nurses.

Infant Mortality in Manhattan and Brooklyn. There has been a marked change in the relative infant mortality in Manhattan and Brooklyn during the past two weeks. Whereas up to the week ended July 31 the death rate of infants under two years for the Summer in Brooklyn had been higher than in Manhattan, during the week ended August 7 the death rate in Brooklyn decreased 22 per cent., while that in Manhattan showed an increase of 39 per cent. over the previous week. In New York for the week ended July 31 the deaths from Summer complaint cases, which cause the greatest mortality among children, were 129, while in Brooklyn there were 137. For the week ended August 7 the death rate for the same cause in Manhattan was 180, and in Brooklyn it was 112. The infant mortality for New York for the month of July for the past three years shows a decided decrease, as is shown by the following table:

	1907.	1908.	1909.
Deaths from diarrheal diseases, under 2 years	1,722	1,755	1,144
Deaths from all diseases, under 2 years	3,206	3,204	2,419
Deaths from diarrheal diseases, under 5 years	1,803	1,709	1,185
Deaths from all diseases, under 5 years	3,675	3,385	2,768

New Medical Law in Arkansas.—The new medical law which went into force in Arkansas on August 6, 1909, provides for more extensive reciprocity privileges between Arkansas and other States as follows: The boards may, at their discretion, arrange for reciprocity in license, with the authorities of States and Territories having requirements equal to those established by the Arkansas boards, and every person desiring license under reciprocity must make application to the secretary of the board representing the school of medicine from which he graduated. License may be granted applicants for license under such reciprocity on payment of $25. All boards are authorized to revoke licenses for the following reasons: Chronic and persistent inebriety, the practice of criminal abortion, either as principal or abettor; conviction of a crime involving moral turpitude; publicly advertising special ability to treat or cure chronic and incurable diseases; the presentation to the board of any license, certificate, or diploma which has been legally or fraudulently obtained, or the practice of fraud or deception in passing an examination. It is also

provided that physicians charged with any of the above may be given a hearing before being proceeded against. The law provides also that any member of the medical boards may grant a temporary permit to practise medicine between sessions of the boards, upon satisfactory proof of the applicant's ability, and upon the payment of the regular fee for examination.

The Iowa State Board of Health has recently made radical changes in the sanitary laws of the State. The sanitation in cases of contagious diseases is to be left largely in the hands of the attending physician. He attends to the disinfection, which is at the expense of the patient. The county also is relieved from the expense of quarantine for smallpox, the patient being obliged to pay all expenses of physician, nurse, and attention. Reporting, placarding, and disinfection for measles, mumps, whooping cough, typhoid fever, consumption, and pneumonia are discontinued. The only diseases over which the authority of the State Board now extends are scarlet fever, diphtheria, smallpox, cholera, leprosy, epidemic cerebrospinal meningitis, and bubonic plague. The period of quarantine is markedly reduced in these diseases. Smallpox patients may be released as soon as the peeling process is completed, and quarantine for scarlet fever shall be raised on recovery, to be certified to the health officer by the attending physician. Diphtheria patients may be released six days after the membrane disappears from throat and nose, providing two consecutive cultures are negative.. The wage-earner in a family quarantined for diphtheria may go and come, but must change his clothes and bathe face and hands with a disinfectant before leaving the premises. Practically the only point in which the laws retain their former rigidity is in the matter of consumption in the schools. Tuberculous students and instructors are forbidden to attend any public or private school. The reason given for this marked reduction in the rigidity of the sanitary laws is that the former laws were so expensive to enforce that the counties could not afford to live up to them.

Toronto General Hospital.—Arrangements have been made between the boards of the Toronto General Hospital and the University of Toronto by which the university is to pay to the hospital the sum of $700,000. In return for this the new hospital is to be built in close proximity to the university, and the professors and heads of departments in the university are to be *ex-officio* heads of the services in the hospital. The total cost of the new hospital will be in the neighborhood of $2,200,000, of which $1,900,000 has already been subscribed.

Sea Breeze Hospital for sick infants and their mothers at West Coney Island, New York, will remain open until September 10 this year, instead of closing at the usual date of August 31.

New Hospitals.—A number of millionaires around Lake Geneva, Wisconsin, have taken steps to build a modern hospital. Nearly all of the capital stock of one hundred thousand dollars already has been subscribed. The hospital is to be located on a hill overlooking the east shore of the lake adjoining the property of Otto Young. The Board of Directors of the Lutheran Deaconesses' Home in Chicago has completed arrangements for a new $75,000 hospital, to be built adjoining the old home at Haddon Avenue and Leavitt Street. A donation of $5,000 has been made by the Illinois Steel Company to the South Chicago Hospital, to be applied toward its indebtedness.

Charitable Bequests.—By the will of the late Col. Thomas Emmett Addis of New Haven the following institutions in New Haven received bequests: The New Haven Hospital, $100,000; Grace Hospital, $100,000; Connecticut Training School for Nurses, $5,000, and New Haven Dispensary, $5,000. After the distribution of a few other minor bequests the residue of the estate, valued at $400,000, is to be divided between the New Haven Hospital and the Grace Hospital. By the will of the late John Edward Brown the Perkins Institute for the Blind in Boston receives $100,000, the Gwynne Temporary Home for Children in Boston $20,000, the Industrial School for Crippled and Deformed Children in Boston $20,000, and the Home for Incurables in Chicago $50,000.

The Medical Society of the Missouri Valley will hold its annual meeting at Council Bluffs, Iowa, on September 9 and 10, 1909. Dr. C. B. Hardin is president of the society, Dr. Charles Wood Fassett is secretary, and Dr. V. L. Treynor is chairman of the committee on local arrangements.

The Upper Peninsula Medical Society, meeting at Calumet, Mich., on August 4, elected the following officers: *President*, Dr. E. T. Abrams of Dallas Bay; *Vice-Presidents*, Dr. R. Binne of Sault Ste. Marie and Dr. John McRae of Calumet. The next meeting will be held at Sault Ste. Marie.

The Waldo County (Me.) Medical Society was organized at a meeting held at Belfast, Maine, on July 29, 1909. The society will hold meetings quarterly, and will be a branch of the State association. The following officers were elected: *President*, Dr. A. E. Kilgore of Brooks; *Vice-President*, Dr. Eugene Stevens of Belfast; *Secretary*, Dr. Jesse Cook of Unity; *Treasurer*, Dr. O. S. Vickery of Belfast. A Board of Censors was appointed to receive applications of members, composed of Dr. A. E. Kilgore of Brooks, Dr. C. R. Hines of Searsport, and Dr. D. P. Hurd of Thorndike.

Obituary Notes.—Dr. Lewis Balch of New York City died on August 9, 1909, aged 62 years. Dr. Balch was educated at McGill University and the College of Physicians and Surgeons of New York, receiving his degree from the latter institution in 1870. For many years he practised as a surgeon in Albany, holding at various times the position of surgeon to different Albany hospitals, Professor of Anatomy and Medical Jurisprudence in the Albany Medical College, Health Officer of Albany, and Secretary of the New York State Board of Health. At the outbreak of the Spanish-American war Dr. Balch went to Cuba as surgeon of the Second Regiment, New York Volunteers, and later to the Philippines as brigade surgeon with the rank of major. Returning from Manila, Major Balch was put in charge of the sanitary improvements at Colon, Panama, in which work he made for himself an enviable reputation. Since then he has lived in retirement at the Army and Navy Club in New York.

Dr. Joseph W. Southall of Amelia, Va., died at his home August 2, 1909, aged 77 years. Dr. Southall was prominent in his profession and in Virginia politics, having served in the State Senate for several terms, and also as State Superintendent of Public Instruction.

Dr. W. L. Chester of Jackson, Tenn., died on

July 26, 1909, at Memphis, Tenn., aged 50 years. He was a graduate of the University of Louisville in 1879, since which he has practised in Jackson.

Dr. Sarah Hackett Stevenson of Chicago died in that city on August 14, 1909, aged 66 years. She was educated in the Illinois State University and the South Kensington Science School in London, and received her M. D. from the Woman's Medical College in 1873. Dr. Stevenson was the founder of the Illinois Training School for Nurses, and a promoter of the Home for Incurables, the first woman to be appointed instructor in the Northwestern Medical College, and also the first woman member of the American Medical Association. She was a delegate to several international medical congresses, and the author of a work on biology.

Dr. Ignatius Donnelly of St. Paul died in Minneapolis July 31, 1909, aged 51 years. He was a graduate of the Jefferson Medical College in 1883, and had practised until a few years ago in St. Paul as an eye and ear specialist, when his health required his moving to Butte, Mont.

Dr. Francis E. Roche of Ogden, Utah, died of blood poisoning at his home on July 31, 1909, aged 67 years. He was born in Ireland, and received the degrees of Bachelor of Arts and Doctor of Medicine from Dublin University. He was also a Fellow of the Royal College of Surgeons, and for seven years surgeon major of West Essex. On coming to America in 1876 Dr. Roche settled at Oakland California, but nine years lated moved to Utah.

Dr. Joseph Alison Scott of Philadelphia died of heart disease at Northeast Harbor, Maine, on August 13, at the age of 44 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1889, and he later served as resident physician to the Pennsylvania Hospital and the Johns Hopkins Hospital. He was for a time Medical Examiner for the Penn Mutual Life Insurance Co. and Professor of Clinical Medicine in the Philadelphia Polyclinic and College for Graduates in Medicine. He has been for a number of years one of the attending physicians to the Pennsylvania Hospital and also Clinical Professor of Medicine in the University of Pennsylvania. He was a capable clinician and he had made numerous valuable contributions to medical literature.

Correspondence.

BLOND IDIOTS.

To the Editor of the Medical Record:

Sir:—I have read with great interest Dr. Woodruff's paper "Who Are the Unfit" in your August 7 number. His book "The Influence of Tropical Light on White Men" set me to thinking along these lines. Twelve years of my experiences have been among feeble minded and epileptic children, 3,000 of these unfortunates having passed my way. The Mongolian idiots, who average 40 in 1,000, and are on the increase, are blonds, but two exceptions having occurred in 126 cases, and those two had gray eyes. Heredity does not play a part in this form of idiocy. The congenital feeble-minded in this 3,000 were, with few exceptions, blonds, and those exceptions were not true brunets. The feeble-minded who were made so by illness were brunets, adding weight to the fact that brunets have greater vitality. Another striking fact concerning the Mongolian idiot, a fact nowhere mentioned in connection with his characteristic hand, is that the forefinger is longer than the third, with few exceptions, and those had that finger as long as the third and were the darker blonds. Among normal children I find but 20 long forefingers among 1,000, and two-thirds of these are girls. These children are of high moral development, and are among the best scholars as to school work.

Bertha C. Downing, M.D.

Lexington, Mass.

OUR LONDON LETTER

More Congresses — Health — Medical Meeting — French Doctors in London—Obituary.

(From Our Regular Correspondent.)

London, July 30, 1909.

A second week of congresses. The British Medical at Belfast has occupied it throughout, but the others, noticed in my last, have extended their proceedings into a part of it. The anti-vivisectionists held their threatened second demonstration in the park, and there, as at the meetings under cover, violent language was repeated.

The Health Congress at Leeds had a joint meeting of the Preventive Medicine and Child Study sections to discuss the control of infectious diseases among school children. Dr. Ralph P. Williams said personal contact was one of the chief factors in the spread of infection and was promoted by the use of long desks, though, of course, he referred to the more potent causes as deficient ventilation, etc. He strongly criticised the present system of basing government grants on attendance, which, like the prize system, induced parents to send the children to school when ailing, for then it often turned out that the early stage of infectious disease was begun. Parents and teachers should be taught this, and to recognize suspicious cases. Dr. Thomas declared emphatically that the control of infection had shown no improvement, although great advances had been made in other work by the health authorities. Isolation and disinfection were inadequate and the indiscriminate closing of schools useless, and therefore foolish. The need was to exclude individual children, and parents should be asked to notify the teacher immediately of any indisposition. Dr. T. Orr had investigated the tenacity of existence of the diphtheria bacillus on slate, wood, and paper, and he told the audience that its activity continued for several days during exposure to diffused light and for a much longer time when kept in the dark. Dr. Gibson did not think much of isolation in scarlet fever, but relied rather on more efficient notification. Several speakers mentioned the success of abolition of prizes in certain localities, and the hope was expressed that the Board of Education would take action as the result of these discussions.

At another meeting Dr. Kaye computed that of the 6,000,000 children attending schools less than 4,800,000 could be properly described as sound in body and mind, and what amazed him was that a large proportion of the infirmities were removable, or, if taken in time, preventable.

At the concluding meeting of this congress Dr. Brathwaite, of the Home Office, made the important announcement that extensive changes in the law relating to inebriates might be anticipated in the near future, as the departmental committee had recently reported in favor of extending the existing powers of dealing with them. He said every inebriate was a potential criminal, a burden on public funds, a danger to himself and others. Moreover, by precept, example, neglect of his family, and the procreation of his species was contributing to the supply of drunkards, to the detriment of the national welfare. The doctor added that in his twenty-five years' experience he had received less aid from total abstainers than others, for their cry was total universal abstinence, short of which nothing satisfied them, but years must elapse before that could be reached, if ever. In the meantime the evil of multiplying drunkards goes on and no cry is raised against the unsatisfactory state of the law. Go on, he said, with preventive measures, but do not neglect curative and protective legislation, which will not only pay at once, but are necessary from all standpoints, Christian, humanitarian, and economic.

The Pharmaceutical Conference has also held its annual congress this week. It opened on Monday at Newcastle-on-Tyne, when addresses of welcome were given by the university, the municipality, the local medical profession, and, of course, the local pharmacists. On Tuesday Mr. J. F. Tocher delivered his presidential address in Armstrong College to a large gathering. He held that most of their difficulties were economical. Referring to the tax on alcohol, he said if it were to extend to a solvent for drugs it would economically prove injurious to hospitals, clubs, and the sick poor generally. Instead of taxing necessary medicines ordered through the legitimate channel—the medical profession—if the Government would put a heavy tax on nostrums and medicines not so ordered

the State would not only do a service to humanity by diminishing the misuse of drugs, but furnish the Pharmaceutical Society with funds to enforce the law and protect the public.

The British Medical, as I said, extended over the week, though the sections only occupied three days. What with dinners and entertainments of all kinds, the "doctors' picnic" is a sort of week's dissipation salted with science, this last in fifteen sections, one additional having been appointed during the year. The special reporters you have to represent you in the more important sections and general meetings will supply you with an account of all those proceedings. As to the more specialized sections, they can wait for reports or comments on the discussions as may seem desirable. The addresses on "Medicine," "Surgery," and "Obstetrics," by Dr. Philip, Mr. Barker, and Sir J. Byers, were, of course, the *pièce de resistance.*

A party of about forty French doctors are in London this week in connection with l'Enseignment Médico-Mutuel International, of Paris. The president and founder, M. Etienne Bazot, is of the number. They are visiting the royal colleges, several of the hospitals, the Natural History Museum, etc. These will occupy them from Thursday until Sunday, after which they will make a tour to Oxford, Cambridge, Edinburgh, and the other university cities. They expect to return to Paris on August 15.

The death is announced of William Brown, F.R.C.S. Ed., Medical Officer of Health for the city of Carlisle. He was educated at Edinburgh and qualified at the two royal colleges. Later he took the English College of Surgeons membership. His reports on the health of Carlisle and other contributions to medical literature were important.

Dr. Rayner Winterbotham Batten, who died on July 15, aged 74, was consulting physician to the Gloucester Royal Infirmary, on the staff of which he had been for thirty-three years. He took an active part in the social life of the city where he lived, and was foremost in all philanthropic and religious movements. He was working only two days before his death from heart failure.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

AUENBRUGGER CENTENNIAL—PRESERVED MOTHER'S MILK—PATHOGENESIS OF ARTERIOSCLEROSIS—OSMOTIC POWER OF THE INTESTINES—HYPOPHYSIS EXTRACT—TEMPERATURE OF HEART AND LUNGS—BLOOD REACTION FOR TUBERCULOSIS.

VIENNA, July 15, 1909.

At the centennial of the death of Leopold Auenbrugger there was unveiled on the house in which he died a memorial tablet, founded by the Vienna Medical College. Auenbrugger, born in Graz on November 19, 1722, was the discoverer of percussion of the chest. His article, *"Inventum Novum,"* published in 1761, describing his discovery, was ignored by the contemporaneous clinicians, especially by Gerhard van Swieten and Anton de Haen. These two latter sought to bury the fact so that this blessed discovery would have been entirely forgotten with Auenbrugger's death had not Jean Nic. Corvisart, Napoleon I.'s personal physician, recognizing its great significance, given due praise to the neglected and often derided old man in an article on the discovery, confirmed and perfected by himself. In France percussion was zealously used and added to by Laennec through his introduction of auscultation. It was Joseph Skoda, however, in Vienna who put it on a scientific basis.

Ernst Mayerhofer has been making some feeding experiments with preserved woman's milk. The need of a method to preserve mother's milk speaks for itself. Mayerhofer proposes a modified Budde procedure to accomplish this. To 400 c.c. of mother's milk he adds 0.1 c.c. of perhydrol. If the reaction is evil he adds magnesium peroxide besides the hydrogen peroxide. With proper care of the milk (weekly repetition of the process and, eventually, neutralization of that which has become acid) it is possible to give to infants mother's milk which is months old. The results at the Kaiser Franz-Joseph Children's Hospital in Vienna demonstrate that it is possible to make woman's milk stable by sterilization without its losing any of its qualifications as a nutriment, and that preserved mother's milk serves much better than cow's milk as food for premature infants. In this manner every infant hospital may be emancipated from the danger of a temporary loss of wet nurses; indeed, they can nourish infants naturally and with good results for some time without wet nurses.

Prof. Dr. Biedl and Dozent Dr. Ludwig Braun have made some investigations into the pathogenesis of arteriosclerosis, in which they tried especially to clear up the mechanical cause of the condition. They were able to produce marked changes in the thoracic aorta, especially in its ascending portion, in rabbits, by repeated compression of the abdominal aorta. The compressions were made on normal rabbits by pressing the aorta against the spinal column above the origin of the renal arteries once daily for a period of about two minutes. If the pressure was made below the renal vessels the changes in the thoracic aorta did not occur. From these researches it was concluded that circulatory changes occurred from the compression of the aorta which entailed changes in the aorta in some manner which required further investigation. In further studies the authors were able to produce sclerotic changes in the aorta and the smaller vessels by feeding on a dry diet of oats. Further investigations will now be carried out to determine to what extent these changes are dependent upon a thickening of the blood. It is stated, finally, that sclerotic changes may be produced in the complete arterial vascular system of rabbits by means of absolute fasting.

Ernst Pribram has investigated the intestinal wall as an osmotic membrane in acute and chronic enteritis. If one uses the intestine as a colloidal membrane and tests its permeability for crystalloids (salt and sugar) in the fresh, unchanged state, one finds that in individuals (both animal and human infants), with chronic enteritis, its permeability is markedly decreased, while in acute enteritis it is increased to a high degree. The experience of the clinicians, galactosuria in infants with acute enteritis, febrile attacks on feeding salt or sugar, and the brilliant results from osmodietetic therapy would lead one to expect that conditions exist in the living organism quite similar to those found *in vitro.* But not only crystalloids, but also colloids, albumin, ferments, toxins, etc., diffuse much more rapidly through the acutely inflamed gut than through the healthy one. The cause of this difference lies in the condition of swelling (acute enteritis), and in the thickness of the superficial layers (chronic enteritis). From this Pribram proposes to administer in acute enteritis a diet as poor as possible in salt and sugar, but in chronic enteritis to increase the osmotic pressure by diets rich in these substances and so aid absorption.

Professor von Frankl-Hochwart and A. Frölich have studied the action of hypophysis extract upon the sympathetic and voluntary nerves. The injection of hypophysis extract, carried on in cats, dogs, and rabbits, stimulates the bladder to contraction in a high degree, and simultaneously increases its irritability to the faradic current working on the N. pelvicus of the voluntary nervous system. The N. hypogastricus belonging to the sympathetic system is not influenced by it. The rabbit's uterus is similarly markedly affected by hypophysis extract. Repeated injections have a weaker effect than the primary one. The effect is independent of the blood pressure. The extract does not affect the salivary glands, the vagus, or the N. erigens. The pupils are markedly contracted. The extract of the hypophysis acts in a different manner from suprarenal extract. The latter is a stimulant of the sympathetic system; the former stimulates some voluntary and some sympathetic nerves, and its action is especially marked upon the abdominal organs. In disease of the hypophysis disturbances of the genital power occur, and, with sufficient involvement of the hypophysis, this may be completely lost. Bladder disturbances are not uncommon with hypophysis tumors without acromegaly, possibly due to an absence of secretion of the hypophysis. The extract is not poisonous. It is possible that the clinicians may be able to make use of this property of the extract to increase the excitability of the bladder and uterus.

Professor Exner has been investigating the relation between the temperature of the heart and that of the lung. In cold-blooded animals the heart is separated from the lungs, and in many surrounded by the liver. In warm-blooded animals and in man it is almost completely surrounded by the lungs, and in birds by the pneumatic sac. This situation of the heart has the result of cooling the heart muscle, which, by its activity, produces much heat, and prevents overheating. The

human lungs remove from the body daily in the neighborhood of 322 calories, of which 80 are used up in warming the inspired air and about 242 in saturating it with water vapor. When the body is threatened with the danger of hyperpyrexia the lungs remove more heat by faster breathing—thermic dyspnea—by which more air is inhaled than normally. The cardiac work amounts to approximately 10,000 kilograms daily, of which two-thirds is converted into heat, by which about 70 calories are produced. The heart gives over a part of the superfluous heat to the neighboring organs. The researches of Yoshimura in the Vienna Physiological Institute on the temperature relations of the heart and lungs, made by means of thermal needles stuck into the organs, show that the ventricular wall is in the neighborhood of 0.5° warmer than the lungs, and that different localities in the lungs are cooler in proportion to their distance from the heart. The wall of the left ventricle has a higher temperature than the blood contained in it; when the heart is laid bare this may reach as high as two degrees. The blood in the left ventricle is colder than that in the right, since the latter has been returned from portions of the body in which active metabolism is going on. The heart gives off from its surface one-tenth to one-fifteenth of the heat which it produces. When one prevents the cooling of the heart by the lungs by surrounding it with dry cotton, as a poor heat conductor, the temperature of the heart rises; it beats faster and then stands still; on removing the cotton it begins to beat again. The right heart is not surrounded by the lungs in man; the sudden cooling is of less significance here, as the right ventricle easily gives off heat on account of the thinness of its wall, and produces but little, its working being relatively slight, only one-seventh to one-eighth of that of the left ventricle.

Based upon 800 cases of various diseases, Erich Stoerck has found a test which is positive in some 60 per cent. of the cases of phthisis. The serum of the patients, on addition of twice its volume of ½ per cent. carbolic acid solution in normal saline, causes a precipitate after 10 to 12 hours in the thermostat. In some cases a precipitate occurs if one adds to the serum a sufficient quantity of fresh bacillary lipoid in salt solution, whether it be obtained from the fatty portion of the tubercle bacillus or from yeasts. By an emulsion of the ethereal extract of 0.5 gm. of lipoid-rich bacilli in 250 c.c. of ½ per cent. carbolic acid saline solution, a reagent is obtained, which, in about 75 per cent. of all cases of pulmonary tuberculosis (the reagent being mixed with the serum in the proportion of 2 to 1), causes a precipitation after a few hours in the thermostat. This precipitation also occurs in cases of far advanced tumors, in severe diabetes, in the early stages of infectious diseases, and after the injection of large amounts of milk. It is necessary that the test be made in the morning, when the stomach is empty, 10 to 15 hours after the last meal containing milk or fat. Membranous plates also occur occasionally in the serum. These have nothing to do with the fine granular or flocculent precipitate, and must not be mistaken for it. The material which gives the reaction is apparently of a fatty nature. Both phenol and sodium chloride are necessary for the typical reaction. The effort to replace phenol by other acids, as hydrochloric, oxalic, and acetic, gave no definite results. When isotonic cane sugar solution was used instead of the sodium chloride the reaction failed in nearly every case. Other bodies than the lipoid obtained from bacteria did not stand the test, though now and then lecithin, sodium glycocholate, and vaseline gave a precipitate. The reaction would be of practical value in the differential diagnosis between early pulmonary tuberculosis and other diseases, with the exception of tumors with degenerative changes, severe diabetes, and acute infectious diseases. The reaction appears to be conclusive only if it occurs constantly on different days.

Mercury and Sulphur.—D. Respighi finds that sulphur acts as an antidote to mercury in the intestinal canal and when sulphur waters are being drunk it is found that the patient will tolerate a larger amount of mercury than when they are not in use, without the occurrence of mercurialism. Sulphur is not only an antidote to mercury in the intestinal canal, but also to the mercury circulating in the blood. Whenever we have symptoms of mercurial poisoning in syphilis we should make use of the sulphur waters as an antidote and eliminant.—*La Riforma Medica*, February 24, 1908.

Progress of Medical Science.

The Boston Medical and Surgical Journal, August 5, 1909.

The Etiology of Tumors Considered from the Standpoints of Congenital Tumors and Tumors Following Repeated Injuries.—S. B. Wolbach states the hypotheses of Cohnheim, Ribbert, and von Hansemann. After considering metaplasia of epithelium, heterotrophic proliferation of epithelium in chronic inflammatory processes, carcinoma following well-known pathological processes, carcinoma associated with unusual occupations and practices, and carcinoma following *x*-ray exposures, the author summarizes as follows: "I have endeavored to present a few data which support the belief that congenital tumors and tumors of infancy and early childhood most commonly take origin from isolated or misplaced cells. At least we have very positive evidence that certain tumors, such as teratomata, hypernephromata, mixed tumors of the kidney and parotid, and the retinal tumors arise from such errors of development. I have endeavored to show that in the cases of *x*-ray carcinoma and a few other instances, such as Bilharzia disease and Kangri carcinoma, there is a proved casual relationship between malignant tumors and antecedent pathological processes. The more peculiar the source of the injury, the greater is the value of the evidence when the association is marked by a strikingly large number of cases. The similarity in the evolution of the skin carcinoma in widely different kinds of exposures points to a common underlying process whatever the nature of the injurious agent. In the case of *x*-ray carcinoma and Bilharzia carcinoma, there is a proved similar antecedent pathological process. *X*-ray carcinoma is to be regarded as the first instance of an experimentally produced malignant tumor. Its occurrence, following definite lesions of the skin, of a continuous and progressive character, places the whole subject of carcinomata following repeated injuries upon a firm basis. It designates this field of investigation as the most promising one for research into the origin of carcinoma, because we have at least one and perhaps several examples of proved relationship. The facts presented do not speak for belief in simple trauma as a cause of tumor production. They do indicate that long-continued progressive lesions of connective tissue supporting epithelium are responsible for the acquisition of malignant properties by the epithelium. This belief is not so far removed as it would first appear from the hypothesis of von Hansemann, who believes that the malignant property of epithelium is a primary disease. There is no incompatibility in a theory which holds to the idea that similar properties may be acquired by years of changed environment and nutrition. It may be said that no series of experiments upon animals, in the attempt to produce tumors, has ever been carried out which in any way approached duplication of those conditions we find in man associated with the production of cancer. The element of time is perhaps the most important factor. Many years always elapse between the onset of the antecedent pathological process and the occurrence of cancer. In the case of *x*-rays ten years is perhaps the shortest period. The magnitude of the problem and the value of results should justify the expenditure of time and money necessary to more adequately investigate this field of the cancer problem.

Superficial Dermatitis of the External Auditory Canal.—Clarence John Blake says that under conditions of maceration the epithelial layer is easily separable, both from the outer surface of the drumhead and from the inner end of the auditory canal. Normally it disposes of its detritus in the form of flattened epithelial scales, not after the usual manner of disposal in other parts of the skin, but by a well-defined movement or progression which carries the effete material toward the outer end of the canal until it is there mechanically excluded. In a series of investigations the lines of movement of this epidermal layer, so far as the drumhead is concerned, were definitely mapped out several years ago, the general lines of movement being from the center toward the periphery, upward and backward, and then outward along the posterior wall of the canal. Recent investigation also shows that the corresponding movement of the epidermal layer of the external auditory canal is mainly along the superior posterior wall, with a gradual inclination downward toward the inferior wall, which is reached at the point of junction of the cartilaginous and osseous canals. The rate of movement of the epidermis of the drumhead from the center of the drumhead to its periphery is much more rapid than the movement along the canal wall, and, moreover, this latter is appreciably slower toward the end of the course toward the isthmus than at the beginning at the inner end of the

canal. A superficial dermatitis of the external auditory canal affects principally this epidermal layer, though the primary exhibition may be through the underlying derma, the result of a local irritation or the symptom of a systemic condition. In acute inflammation the primary mechanism is a dermal hyperemia with serious transudation and elevation of the thin dermal layer which, under maceration, disintegrates and, mixing with the serum, affords an outflow macroscopically simulative of pus. Under these conditions the most effective first treatment is thorough cleansing by means of syringing with a weak, warm solution of soda bicarbonate, followed by careful drying with sterile absorbent cotton, this process being repeated at intervals until the exfoliated epidermis has been entirely removed. When this has been effected the denuded surface should be painted with a solution of silver nitrate of a strength of 60 to 80 gr. to the ounce. In the subsequent treatment care should be taken to search for any spots of ulceration or small areas of granulomata in order that they may be touched with a stronger silver solution. The exfoliation of the outer portion of the canal should be treated by scrubbing with weak peroxide and soda bicarbonate solution, followed by application of alboline. In chronic forms of epidermal disturbance where the epidermal layer seems to have lost its normal progression, or to have it so much impaired as to result in the accumulation of superimposed epidermal layers *in situ*, these layers should be carefully peeled away from the canal wall and successively removed by means of forceps, the underlying hyperemic surface being searched for areas of granulomata, with a view to their treatment with silver nitrate. In all these cases it is well to keep the individual under observation in order to guard against recurrences, either of the acute form or of the resultant epidermal accumulations, until the skin has resumed its normal functions.

Psychasthenia.—A. H. Ring summarizes his paper as follows: (1) Janet, who coined the word "psychasthenia," intends to include under the term obsessions, manias of doubt, tics, agitations, phobias and the deliria of contact, states of anxiousness, neurasthenias, and bizarre sensations of strangeness and depersonalization. These he would group together into a grand pychosis similar to hysteria and epilepsy. (2) Psychasthenia is at base a disturbance of the feelings, the will, and perception, and may range from mere eccentricities in the superficially normal through mild depression to melancholia and dementia. (3) There are two types: 1, Those in which the disturbance shows itself, principally in motor fatigue, and 2, those in whom the principal affection is in the sensory motor and emotional sphere, the latter offering the less favorable prognosis. (4) Phobias result from an unhealthy, prolonged feeling tone of depressing ideas and may be conscious or subconscious. (5) Doubts and indecision are evidence of fatigue of the higher centers which preside over formative and newly synthetized associations. The final judgment is thus rendered difficult or impossible, and the victim finds himself in a state of vacillation and with a tendency to revert to the lower and simpler associations long formed. Weakened cerebral inhibition also plays its part. (6) Obsessions and impulsions are the emotional result of the above factors, and show themselves principally as a failure to inhibit the feeling-tone of ideas automatically repeated, yet the all-pervading asthenia checks the impulses short of accomplishment. (7) Psychasthenia should be differentiated from hysteria, epilepsy, dementia præcox, manic depressive insanity, and paresis. (8) The treatment is largely prophylactic and educational. Physical and hygienic measures should be combined with explanation, persuasion, and encouragement. Logic appeals to these patients, but they are not good hypnotic subjects.

New York Medical Journal, July 31, 1909.

Achylia Gastrica and Insufficientia Pylori.—A. L. Benedict refers to the discussion between Dr. Mark I. Knapp and Dr. Max Einhorn in regard to the use of the term achylia gastrica. Speaking generally he does not believe that it is possible to give a description of either pyloric insufficiency or achylia gastrica in the sense of presenting a clinical picture. This does not mean that he has never suspected the occurrence of these conditions in advance or that his conjectures have always been wrong, but that there is no unmistakable characteristic clinical picture of either, and that a diagnosis cannot be made until the examination has actually been made. The writer opposes Dr. Knapp's statement that "the pyloric region is the lowest part of the stomach, hence all ingesta drop there by mere gravitation." In a perfectly normal stomach the pyloric region—but not the pylorus—is only slightly higher than the great curvature; in comparatively slight degrees of atonic dilatation and ptosis it is practically a long way from being the lowest part. He also objects to Dr. Knapp's implication that supermotility of the gastric muscle generally is necessarily associated with pyloric spasm, or that achylia gastrica is necessarily atrophic and insufficiency of the pylorus hypertrophic, or that an exaltation of one function may not coexist with a depression of another function. He agrees, however, with Dr. Knapp's statement that achylia gastrica should not be inferred from the absence of stomach contents an hour after a meal. To sum up, Dr. Benedict believes that there is such a condition as achylia gastrica, and such a condition is insufficientia, or at least, relaxatio pylori. They are absolutely different conditions, having in common only the element of depression of function, which may be functional in the ordinary sense or as secondary to an organic lesion. They are so different that there can be no question of correct nomenclature or interpretation of a single disease or symptom complex, so different that they may exist independently or may coincide in the same case.

Does Zymosia Gastrica Solve the Soil Problem of Tuberculosis?—Dr. Mark I. Knapp presents this report as a result of the study of the gastric condition of one hundred cases of the New York Board of Health Clinic for Pulmonary Tuberculosis. He refers to his paper on Organacidia Gastrica, in which he distinguishes three distinct subdivisions of organacidia gastrica, viz.: organacidia gastrica simplex, gastrosia fungosa, and zymosia gastrica. He has since added a fourth subdivision, namely, organacidia gastric ab amylo, which is the result of eating large quantities of starches, either in the shape of plain bread, or cakes, or potatoes, etc. After describing the experiments Dr. Knapp makes the following deductions: (1) Every case is one of zymosia gastrica: (2) in seventy-eight per cent. of the cases the pylorus is affected; (3) in eighty-six per cent. of the cases free hydrochloric acid is present together with various and abundant growth of microorganisms. One case showed zymosia gastrica many years before pulmonary conditions developed. It would seem that this occurrence of sporulating, budding yeast is rather more than a coincidence, and that zymosia gastrica must bear a certain relation either to the development or to the progress of tuberculosis. The assumption that zymosia gastrica may possibly be held responsible for the soil conditions of tuberculosis is very daring; yet zymosia gastrica apparently constitutes some factor in the condition of tuberculosis. The interest of science demands that we get more information on the subject, and that such of the profession who interest themselves in the scientific research of tuberculosis inquire with special care into the gastric condition.

Tuberculous Infection Through the Tonsils and Adenoids.—A. J. Pratt believes that the tonsils and adenoids are only very troublesome vestigial organs; that they have no beneficial function, are disease producing, and that we are better off without them. The inherent resistance of all mucous membrane to germ invasion, and the bactericidal properties of its secretion give protection, but when there is abrasion invasion takes place. In the crypts and fissures, closed as they often are by secretion plugs and attachments of the pillars and mucous membrane, and swollen by chronic and acute inflammation, the path is opened, and the invading germs go on their way to the lymphatic glands to be destroyed or to establish infected centers. The course of infection is illustrated by Dr. J. Grober's three experiments. In these experiments sterilized emulsion of black Chinese paint was injected into the tonsil, in the first instance in a rabbit, and in the other two experiments in dogs. In the rabbit the glands and lymph vessels were fairly packed with coloring matter. Beyond the zone of the glands and lymph vessels very little coloring matter was found. In the dogs at autopsy the tonsil and loose connective tissues containing the afferent lymphatic vessels of the tonsil were of a deep black color; along the muscles of the neck as far as the hyoid bone, and even beyond the thorax to the parietal pleura, there were streaks of pigment. The lymph vessels of the peritracheal connective tissue and of the esophagus as far as two or three centimeters above the bifurcation of the trachea were also colored. All the lymph glands on the lateral wall of the pharynx, hyoid bone, larynx, along the deep vessels of the neck, and supraclavicular fossa were black. The parietal pleura at the apex showed an exudate. In one dog fibrous exudate was found in the apices of both lungs, thus forming a bridge of inflammatory material from the parietal to the visceral pleura. Coloring matter was present in the exudate. From these experiments Grober builds the hypothesis that tuberculous infection of the apex of the lung may take place via the deep lymphatic chain, the supraclavicular glands, and thence the parietal lymphatic vessels, where an inflammatory exudate is

thrown across to the visceral pleura. The tubercle bacilli travel across this inflammatory bridge and enter the apex of the lung. Dr. Pratt believes that the tonsil and adenoid have more to do with tuberculous infection of the lymphatic glands of the neck, larynx, and lungs than all other sources. The majority of tuberculous tonsils are primary infections; rheumatic fever, acute endocarditis, septic thrombophlebitis, pulmonary gangrene, and other infected conditions have their initial lesion in the tonsil and adenoid. In all tuberculous cases the tonsils and adenoids should be thoroughly removed that the present and future source of infection may be eliminated.

Journal of the American Medical Association, August 7, 1909.

Pulmonary Complications of Laparotomy.—J. C. Munro reviews the pulmonary complications of the last 1,000 laparotomies performed in the Carney Hospital, Boston, showing only 34 cases, of which 11 only were really postoperative in the strict sense of the word. The others had existed before the operation. This very low mortality, 0.4 per cent., was obtained by simple ordinary precautions during the months when the climatic conditions were at the worst. The anesthetic was pure ethyl chloride followed by ether given in as small quantity as possible by the drop method. Analyzing cases, as carefully as he can, he can find no special definite cause or causes that can be eliminated in future. The majority of the patients were out of bed within 48 hours, and were given as liberal a diet as they could be persuaded to take. All were encouraged to move their body and limbs and were given usually plenty of water to keep down thirst.

The Colon Tube and the High Enema.—The question of how far the soft rubber colon tube can be inserted into the bowel to administer an effective high injection is taken up by H. W. Soper, who describes experiments performed by him in which the position of the tube was verified by the x-ray. Sixty cases were examined where it was attempted to pass long blunt end soft rubber tubes, with side openings, into the rectum, the patient being in the knee chest and side positions. The only case in which he succeeded in passing the tube above the dome of the rectum was one of Hirschsprung's disease or congenital idiopathic dilatation and hypertrophy of the colon, and even here it was necessary to use the sigmoidoscope to introduce the tube. He thinks it is only in cases of abnormal development of the sigmoid that it is possible to introduce a soft rubber tube higher than six or seven inches in the rectum. A short tube six inches in length is therefore best for all sorts of enemata when using water for fecal evacuation, and it is possible, as he has frequently demonstrated, to thoroughly cleanse the entire colon by using a large caliber (one-half inch) short tube. It is also best when retention of liquid is desired.

Tuberculosis of the Larynx.—W. E. Casselberry notes the common opinion of the formidable nature of laryngeal tuberculosis, and seeks to establish for this type of the disease, what is now well known in the pulmonary type, that in certain patients Nature develops an adequate resistance which, properly aided, may arrest the disease. In 24 out of 60 cases observed by him, the disease was of the hopeless, non-resistant type. Twenty-two of the 60 patients had some elements of hopefulness in them, their natural resistance being sufficient to cause temporary amelioration and arrest, but not a permanent betterment, as a rule. Of this number, 8 are known to have succumbed in from 3 to 7 years, and 12 more are evidently doomed to follow the same course. Two, however, of this second group have now almost, if not quite, reached a state of permanent arrest of the disease, and one of these is reported. The third group is composed of 11 patients in which the laryngeal lesions are or were in a state of arrest after a lapse of periods varying from four to fourteen years. This does not mean that they are absolutely free from tuberculous disease, but that all progress in the laryngeal symptoms has ceased. Seven of these cases are detailed and 2 of them have been since reported on by another physician than the author. Several other cases are also reported in which death occurred from tuberculosis elsewhere, the laryngeal disease having practically ceased. The above cases show that the prognosis is not altogether bad and that, if the disease is recognized early and properly managed, we will have better results than heretofore. The treatment is described. Locally it consists in intralaryngeal surgical treatment by excision of circumscribed infiltrations and curettage of ulcerated areas; the use of galvanocautery deep punctures, local application of lactic acid and creosote or formalin. Casselberry does not advise external radical operation except under urgent conditions, but not in the presence of advanced pulmonary disease. Mentholated emollient spray is, within limits, a sedative to cough and pain, and suited for home use. Cocain and orthoform combined are effective also to some extent. Systemic treatment with tuberculin by the opsonic method has seemed to him helpful, and in the resistant types the three cardinal principles of open-air life, rest, and forced feeding are more imperatively demanded than in ordinary tuberculosis. Rest to the voice is essential and business dictation and even social conversation must be interdicted. The advantages of climatic treatment also must not be overlooked. Casselberry concludes with the statement that simple tuberculous hyperplasia has not infrequently undergone resolution, and even tuberculous ulcers have occasionally healed. Partial improvement of the patient's condition has also been observed, and the effects of treatment under observation enable us to differentiate the cases in which a hopeful resistance can be looked for. In like manner the non-resistant cases can be recognized, and the patients guarded from privation and hardship of travel and useless surgical intervention.

Tuberculous Hemoptysis.—J. M. Anders presents a statistical study of 5,891 cases of tuberculosis from the records of a number of Philadelphia public institutions, with special reference to the causes and incidence of hemoptysis. The cases, he says, fall naturally under two heads: (a) Those caused by congestion of the bronchial mucosa and lung tissue; and (b) those due to ulceration or erosion of blood vessels or rupture of miliary aneurysms. It is doubtful, he thinks, whether the degree of hyperemia is not greater in other disorders less liable to be accompanied with hemorrhage, and therefore the tubercle bacillus may probably be considered a factor. The early hemorrhages in tuberculosis are rarely dependent on congestion or erosion, the usual source being the pulmonary vessels. In advanced pulmonary tuberculosis his study of the hospital records decidedly supports the view that fatal hemorrhages usually proceed from a ruptured aneurysm or erosion of a pulmonary vessel. He finds in this study of a much larger number of cases than in a former investigation, which gave only 28.7 per cent. of cases of tuberculosis with hemorrhage, that the larger statistics indicate a higher incidence. Thus in a total of 5,302 cases, excluding those formerly analyzed, hemoptysis was found in 1,950, or 36.6 per cent. As stated in his former communication, on cases kept under longer observation, the percentage rises to 28.7 to 41.8 per cent., and taking the complete records of the Phipps Institute this symptom was manifested in 43 per cent. More cases occurred in the total number among males than among females, but prior to the twentieth year of life the ratio was a little higher in the female sex. This corroborates his early findings, that hemorrhage appears earlier in life in the female than in the male. The prognostic significance is also different. Profuse and fatal hemorrhages are less common in females, and this is a matter of some importance and interest. The collective investigations into the seasonal relation of hemoptysis show that, contrary to the preconceptions of most writers, it is most frequent in the winter months, while August, September, May, and March, in the order named, seem to rank next. The Phipps Institute statistics also indicate the same thing, that the steady cold of December, January, and February has no preventive influence as compared with sudden changes and enervating warmth. In 51.5 per cent. the bleedings were recurrent, and in 69 per cent. hemorrhages appeared in the first and early part of the second stage of the disease, or that of ulceration. Mere bloody or blood-streaked expectoration was recorded in 16.5 per cent., and in only 314 was only one hemorrhage specified. These last results are in accord with those from his former investigation.

The Lancet, July 31, 1909.

Chronic "Rheumatic" Myositis.—N. S. Yawger believes that the most frequent cause of the so-called "gouty" or "rheumatic" pain is a form of chronic myositis. In a search of literature he had been amazed to learn of the frequency of the development of chronic myositis in muscles other than those of the head and neck, and his attention has also been attracted to the errors in diagnosis to which this condition had given rise. Among the causes affecting this condition are heredity, climate, and weather. Temporarily infiltrated muscles have been observed in a child two years old. They may appear at almost any time of life, and are common in old age. It is probable that no voluntary muscle enjoys an immunity, but there are sites of predilection, the most common of which is in the muscles of the head and neck. The gluteal, lumbar, and deltoid regions, and calf muscles are often involved. The muscles may be invaded at their points of insertion, or the infiltrations may appear in the bodies of the muscles; at times the infiltration extends to the periosteum to which

the muscles are attached, and also to the fascia. The pathology of these diseased muscles is largely hypothetical. These deposits may develop in muscles that are overworked, in those not sufficiently exercised, in those that are much exposed, and where an injury has been sustained. The symptoms are those of pain, which may be sharp and cramplike, or an aching sensation. If the swollen muscle impinges upon a nerve trunk there may be a true neuralgic pain. At times there is paresthesia. There are often associated symptoms in various parts of the body, as depression of spirits, mental torpor, unnatural drowsiness, marked susceptibility to cold, torpidity of the liver, indigestion, painful spasms of the calf muscles, general myasthenia, pyorrhea alveolaris, and hypersensitiveness of the teeth. There is only one lesion likely to be mistaken for an induration, and that is a gumma. The mistakes to which these rheumatic deposits give rise are numerous. Many cases of cephalalgia are of this variety; involvement of the intercostal muscles has been taken for intercostal neuralgia and pleurisy; in the abdominal wall they have been mistaken for acute and chronic appendicitis, gastric ulcer, abdominal and pelvic adhesions, calculus of the kidney, and floating kidney; involvement of the gluteal region for sciatica and hip-joint disease; in the neck they have been mistaken for swollen glands; the frequently complained of growing pains of children he believes are due to this condition. A number of cases are cited illustrating these mistakes in diagnosis.

A Case of Missed Labor Treated by Abdominal Section.—C. E. Purslow relates the case of a woman, 33 years of age, who had had four children and one missed abortion. On inquiring into her history at the time of her admission to the hospital it was found that there had been no vaginal hemorrhage for a period of more than twelve months. The woman had considered herself pregnant, and had felt fetal movements until about three months before her admission to the hospital. She presented signs of a full term gestation, but there was very little liquor amnii, and the uterus was hard and tender on palpation. The cervix was not typically softened, and the os was closed. It was found impossible to pass a Hegar's dilator or a uterine sound into the uterus. At a loss to explain this the abdomen was opened, and the uterus was removed by panhysterectomy. The patient made a good recovery. The pathologist reported that the uterus was closely molded to the fetus, and that there was barely an ounce of liquor amnii. The fetus had the appearance of a full-term child. The skin was of a dirty brown color and easily detachable; it was covered with a cheesy substance. The bones of the skull were loose and easily movable. The wall of the uterus was about one-half an inch in thickness; the muscle was pale and easily split into layers. The placenta was situated almost centrally over the internal os, and lined the lower two-thirds of the uterus. The specimen was quite odorless, and a thin gray membrane separated the uterus from the placenta, and remained attached to the former when the latter was removed. The walls of the arteries were thicker than usual, many of the large spaces were filled with old thrombi, and in some organization of the thrombi was well marked. Dr. Purslow thinks that the occurrence of missed labor in a case of complete placenta prævia is unique. The obstruction caused by the tough placenta explained the inability to pass a sound or dilator into the uterus.

Incarceration of the Vermiform Appendix Containing a Foreign Body (Pin) in the Sac of an Inguinal Hernia in a Child.—Thomas H. Kellock reports the case of a male child two years and four months old who had a small, hard swelling in the right inguinal region, which seemed to be neither painful nor tender. The tumor could not be moved independently of the spermatic cord, although traction on the testicle did not have much effect on it. There was nothing in the child's condition or history to suggest syphilis or tuberculosis. As there was also an empyema, operation was delayed for a time, until the child recovered and the general condition improved. After separating some of the adherent parts the tumor was isolated, and found to have a pedicle leading up through the external abdominal ring and to be intimately connected with the spermatic cord. On making an incision behind the tumor it was found that a sac had been opened, and immediately under the incision the proximate end of the vermiform appendix was recognized. It was found to be adherent at its distal end, but traction on its proximal end brought down the cecum. With some difficulty the appendix was divided close to the cecum, and the latter returned to the abdomen. The remainder of the tumor was removed. The mass was found to contain the whole of the vermiform appendix; the proximal end was healthy, but the distal end was much thickened, and intimately adherent to the wall of the sac. It was found to contain an ordinary pin which was lying almost transversely to the lumen of the appendix, and the point had perforated all the thickness of the wall of the appendix, and was implanted in the wall of the hernial sac and the surrounding tissues. There was no pus either in the appendix or in the surrounding parts. It is only a matter of conjecture whether the impaction of the pin or the descent of the latter into the hernia was the primary occurrence. It is also a matter of doubt whether there was any causal relation between the perforated appendix and the empyema.

A Case of Angioneurotic Edema Associated with Cirrhosis of the Liver.—S. G. Corner reports the case of a male patient, aged 40 years, who had suffered from swelling of both ankles and pain, which had prevented him from walking for three years. All the veins of the lower extremities, together with the superficial abdominal veins, were varicose and distended, and an enlarged vein was present in each axilla. There seemed to be some degree of cirrhosis of the liver. The urine was normal. Under rest, total abstinence, and Scott's dressing applied to the ankles the patient recovered in three weeks and was able to walk. About a month later he began to have swellings in other parts of the body. Night after night a tumor appeared in a new place; any region seemed to be liable to become the seat of a sudden swelling. The tumors generally appeared at night and were preceded by slight itching. The case was diagnosed as one of angioneurotic edema, and 10 grains of calcium chloride was given three times a day, increasing the dose to 20 grains. In about a month the swellings disappeared, whether as the result of the treatment or not, the writer could not say. The patient has now been perfectly well for four months, though he still retains varicose veins of the lower extremities.

The British Medical Journal, July 24, 1909.

Remarks on Common Types of Sore Throat.—A. Stanley Green calls attention to the difficulties that sore throats present both as to diagnosis and treatment, especially in small children. In considering the sore throat of scarlet fever he enumerates four different conditions of sore throat that are met with. (1) The tonsils, faucial pillars, palate, uvula, and oropharynx are swollen and of a deep red color. Sometimes there is inflammatory edema. (2) The appearance presented may be that of follicular tonsillitis. (3) A definite membranous inflammation may occur; the membrane is soft and leaves superficial ulceration as it disintegrates. (4) Marked and deep ulceration occurs in the septic variety; the ulceration may spread upward to the nasopharynx and downward to the epiglottis and larynx; the soft palate may be perforated or the uvula may slough off. The treatment of sore throat in these diseases deserves more attention than is usually paid to them. The application of whatever fluid is chosen with a brush is preferable to the attempt to use a gargle, especially in children. The physician should make the application at least once a day himself. In these cases it is advisable to douche the nasal cavities, and for this purpose the glass douche is preferable to the spray. As regards diphtheria, the diagnosis is often attended with difficulty, especially when the membrane is confined to one or both tonsils; Dr. Green has met cases in which only one tonsil was covered with membrane, but bacteriological examination revealed the specific organism. It was important that these cases should be recognized. Vincent's angina is a condition met with more frequently than is generally supposed. There are two varieties, but he considers only the ulceromembranous. When a gray or yellowish membrane is formed on the tonsils and palate it is difficult to diagnose the case from diphtheria or streptococcus infection without a bacteriological examination. Acute streptococcus infection can be differentiated from diphtheria by taking a swab, as the membrane is difficult to remove and the surface of the tonsil bleeds when the membrane is removed. In this condition a culture from a swab will give either a pure growth of *Streptococcus pyogenes* or a mixed growth of staphylococcus and streptococcus. He finds it best to give 5 to 10 c.c. of polyvalent serum (P.D.) and to swab the throat with a solution made by dissolving a 10-grain powder composed of equal parts of sodium bicarbonate, sodium chloride, and potassium chlorate in an ounce of water; this should be done every two hours or oftener if necessary. This solution will dissolve this membrane or diphtherial membrane if thoroughly applied. It is quite useless to paint these throats with antiseptic solutions as they only tend to harden the membrane. Retropharyngeal abscess should be opened by means of a 3-inch incision along the posterior border of the sternomastoid muscle. In adults, at any rate, this method is attended

with less risk than opening through the pharyngeal wall. The only condition that could be mistaken for a retropharyngeal abscess in an adult is a large gumma. Chronic retropharyngeal abscess in children is not at all uncommon, and the author always performs the external operation, and, up to the present, has not lost a case. In tonsillitis a careful examination of the heart should be made, and if cardiac trouble is discovered small blisters should be applied over the cardiac area. Gargles are worse than useless in these cases; it is better to give the patient guiacum lozenges to suck freely and to apply a warm alkaline lotion to the throat with a brush several times a day. The author prescribes sodium salicylate, sodium bicarbonate, and ammonium bromide; if there is a high temperature, tincture of aconite is added. There could be no doubt about the expediency of removing tonsils which are the seat of chronic tonsillitis or which have been subject to recurrent attacks of acute inflammation. Dr. Green has made a pair of forceps with the blades cutting up and down so that they might fit in between the pillars of the fauces, which were in danger of being injured if the blades cut from before backwards. In regard to malignant growths sarcoma is the most common one which affects the tonsils. If seen before the glands are affected the tumor can in many cases be shelled from its capsule with little trouble and with little, if any, hemorrhage. Even if ulceration has occurred and the condition of the patient is good an attempt should be made to remove the growth. In the treatment of both sarcoma and carcinoma of this region with the *x*-rays and radium Dr. Green's experience is that not only is the rate of growth not checked, but in some cases it is accelerated. In secondary syphilis of the larynx the best local application is a solution of chromic acid (10 grs. to the ounce). Chronic pharyngitis is sometimes due to some constitutional defect, and its successful treatment depends upon ascertaining the cause. If the granules do not disappear under proper treatment they should be destroyed with the galvanocautery blade, only a few being touched at a sitting. Where the swelling of the inferior turbinated bone causes obstruction the application of the galvanocautery to the mucous membrane of the offending turbinates may cure the condition, but in some cases it may be necessary to remove the anterior one-third of the bone; this may be done under local anesthesia. In doing this, Dr. Green uses scissors which he had made with the lower blade a little longer than the upper one. After the cut is made the loop of the cold snare is passed around the cut end, and by tightening it up the amount deemed necessary may be removed. Dr. Green also discusses laryngitis and the importance of an early diagnosis in laryngeal tuberculosis and malignant disease of the larynx. In intrinsic cancer of the larynx early diagnosis and prompt operation give better results than follow the removal of cancer in any other part of the body. Very excellent results have been obtained since the method of attacking the disease by the external operation of thyrotomy has superseded the older methods of intralaryngeal removal. In extrinsic cancer of the larynx ulceration occurs early and the glands are involved much earlier. Even in these cases an effort should be made to extirpate the disease if the condition of the patient warrants it. It should be laid down as an absolute rule that when an adult complains of hoarseness or alteration of the voice of several weeks' duration, the larynx should be carefully examined, and if there is diminished mobility of a vocal cord, with or without definite tumor, the help of a skilled laryngologist is necessary and should be promptly obtained.

Pneumonia Migrans Involving the Whole of Both Lungs, Followed by Empyema: Recovery.—James Bannerman reports the case of a girl, aged three and one-half years, which lasted for five weeks and involved the whole lung area. The disease affected the three lobes on the right side, commencing at the top, and the two lobes on the left side, commencing with the lower. The last involvement, that of the upper left lobe, was preceded by localized pleuritic effusion. About a week after the subsidence of the last attack sickness supervened and the child began to go downhill rapidly. The left base had never regained its resonance, but it now became absolutely dull, with distant bronchial breath sounds. A few days later an increase in dyspnea led to exploration of the left base, where pus was found. One and one-half inches of the eighth rib was resected under local anesthesia. A large quantity of pus was evacuated. A week after operation defective drainage caused a rise in temperature. The cavity was then irrigated daily with a weak solution of perchloride followed by saline solution, after which the patient made an uninterrupted recovery. Six weeks after operation she was running about with an expanded left lung.

The Causes of Obstruction Producing Cyanosis During the Nasal Administration of Nitrous Oxide.—F. Trewby concludes that cyanosis during the administration of gas in the ordinary cases is merely mechanical, being mainly due to the size and shape of the palate and tongue. The tongue varies from the large flabby to the compact muscular variety. The soft palate is important because of the variability of its length. When these structures give rise to the greatest obstruction to free breathing, the patient has a large, flabby tongue, and a long overlapping soft palate. As the soft palate loses its tone it acts as an inspiratory valve and is pressed down on the base of the tongue during expiration. This may be brought about much earlier if gas is given under much pressure through the nosepiece, as the gas passing back into the nasopharynx forces the soft palate against the base of the tongue, thus making expiration through the mouth impossible. If there is no valve at the upper part of the bag, nasal "to and fro" breathing into the bag commences, the patient gradually becoming cyanosed. If there is a valve to prevent this rebreathing, then the only possibility of respiration is by forcing the nosepiece slightly off the face. It is quite easy to keep this class of patients unconscious with the ordinary nosepiece, but only at the expense of cyanosis. A patient with a small compact tongue and short soft palate can be controlled by placing an expiratory valve in the fauces. Between the two extremes are varieties of tongues and soft palates which during administration give rise to more or less obstruction to respiration, with a corresponding amount of cyanosis or gas anesthesia. Cyanosis causes distension of the large veins of the neck and it is quite easy to imagine how with the increased tension within the cervical fascia occurring in asphyxia the airway here may be completely obliterated by pressing the laryngeal opening against the wall of the pharynx and the space just above the pharynx which is extremely vascular. From the fact of the occurrence of nasal "to and fro" breathing during the induction of anesthesia by nitrous oxide, and since in the later stages of the induction the breathing is almost entirely by the nose, the author concludes that any nosepiece without an expiratory valve on it causes unnecessary obstruction and cyanosis, not only while anesthesia is being induced, but also during the continued administration of the anesthetic.

Rigor Mortis in Stillborn Child.—C. Eglington reports the case of a woman admitted to the Birmingham Maternity Hospital with hemorrhage at eight and one-half months in her eighth pregnancy. She had been quite well and remembered having felt the child move as usual until four hours before admission. On admission no fetal heart could be heard. Delivery was natural five hours from the onset of hemorrhage and the placenta was expelled immediately after the child. Artificial respiration was at once attempted, when it was discovered that the child's body was already rigid. The surface of the placenta was unusually smooth and was covered with recently clotted blood.

Berliner klinische Wochenschrift, July 12, 1909.

Experimental Glycosuria.—Sussenguth reports a series of experiments in which he injected solutions of grape sugar subcutaneously into guinea pigs, rabbits, and pigeons. His results differed from those of Kossa and Pflüger, who obtained diabetic coma. His animals showed no constitutional symptoms which could be blamed directly to the sugar in the blood. There was no polyphagia, polydypsia, or polyuria. There was no coma. The animals all became infected and death resulted from the phlegmona rather than from the toxic effect of the sugar. The urine at no time contained albumin. Glycosuria was present in every case; when the sugar injection was small this was remittant, when it was large, constant. The amount of sugar excreted was but a small per cent. of that taken in, and increase in the injections did not increase the excretion proportionately. At autopsy no gross lesions were found in the kidneys. The general condition of the liver and the storing of glycogen were of interest. Instead of the customary regular diffuse deposit of glycogen, it was very irregular in its content, many cells being quite free and the glycogen appearing in patches. The nuclei contained no glycogen. The pigeon livers, on the other hand, were tremendously loaded with it. In the rabbits and guinea pigs there was a decided increase of glycogen in the heart. This did not occur with the pigeons. There was no increase of glycogen in the kidneys. The author concludes that the injections of sugar had no toxic effect on the animal organism, and that the normal glycogen content of the organs was not altered in the manner in which it is in diabetis.

Book Reviews.

American Pocket Medical Dictionary. Edited by W. A. Newman Dorland, A.M., M.D., Assistant Obstetrician to the Hospital of the University of Pennsylvania, Fellow of the American Academy of Medicine, etc. Containing the Pronunciation and Definition of All the Principal Terms Used in Medicine and the Kindred Sciences, Along with Over 60 Extensive Tables. Sixth Edition, Revised and Enlarged. Philadelphia and London: W. B. Saunders Company, 1909.

In this edition of Dorland's convenient pocket dictionary there are twenty-four more pages than in the fifth edition, yet the use of thinner paper has enabled the publishers to reduce the thickness of the book by a quarter of an inch. So far as convenience of handling, print, paper, and binding of the book, it is all that could be desired, but the work shows haste in compilation that does not altogether recommend it to the man who wants a correct definition and not merely a synonym. For example, under Dubini's disease one is referred to myelitis convulsiva and electric chorea; electric chorea is defined as Dubini's disease, and myelitis convulsiva is not defined at all. Reissner's canal is said to be the cochlear canal, which it is not. Oturia is defined as a "discharge of urine through the ear." Why not define it as a discharge of the ear through the urine? This would be a more picturesque and no more impossible performance. This ridiculous word, as well as sutika, moyrapuama, and a number of other terms might have been omitted with advantage. The faults are not numerous, but it is a pity to spoil what might be so good a book with too hasty compilation.

Graphic Methods in Heart Disease. By John Hay, M.D., M.R.C.P., Assistant Physician Liverpool Royal Infirmary. With an Introduction by James Mackenzie, M.D., M.R.C.P. London: Henry Frowde, Oxford University Press. Hodder & Stoughton, 1909.

The use of the polygraph has opened up a new field of study which is full of promise in the diagnosis of obscure disturbances of cardiac function. Formerly the ear detected the presence of valvular lesions, as well as alterations of rhythm, and the sphygmograph showed changes in force and rhythm of the contractions of the left ventricle, but what was being done by the atria and the right ventricle was a matter of conjecture. The polygraph, however, with its simultaneous tracings of the jugular and liver pulses, together with the apex beat and the radial pulse, gives one a clear comprehension of the work of the heart as a whole; it is writing a new treatise on the action of this central organ of the body and explaining many of its vagaries which puzzle and often disconcert the clinician. But the writing of the polygraph is not an open book; its language is new and must be learned by the investigator. This work of Dr. Hay may be compared to a grammar or a phrase book, helping one to master the vocabulary and the idioms of the strange language and to interpret its mysterious and otherwise unintelligible phrases. The author has done his difficult and path-breaking task well, and students of the modern methods of diagnosis in diseases of the heart will find it an invaluable aid in their work.

Syphilis und Nerven System. Neunzehn Vorlesungen für praktische Aerzte, Neurologen und Syphilidologen. Von Dr. Max Nonne, Oberarzt am Allgemeinen Krankenhaus. Hamburg-Eppendorf: Zweite vermehrte und erweiterte Auflage. Berlin: Verlag von S. Karger, 1909.

The first edition of this valuable book appeared about six years ago. The present edition has been considerably enlarged and improved and brought up to date. Certain alterations have been necessitated by recent discoveries in pathology and advance in clinical diagnosis and treatment. Among the discoveries of the past six years bearing on the subject which have been accepted and utilized by Dr. Nonne in this new edition, and mentioned by him in his preface, we note: the isolation of the causative germ, *Spirochæta pallida;* the origin and development of cytodiagnosis and spinal fluid investigation, and the diagnosis of syphilis by the so-called Wassermann reaction. The author's own studies and investigations, modestly set forth in the first edition, having for the most part stood the test of time, are here more fully and authoritatively discussed. While some things which we had come to look upon as settled have had to be unlearned. These the author clearly points out, and things still under discussion he seems to treat in a fair manner. His lectures are interspersed with records of cases. Many of the illustrations are original. The text comprises 641 pages, while 58 pages are given over to bibliography and, what is not always found in German books, a carefully prepared cross index.

Experimental Pharmacology. A Laboratory Guide for the Study of the Physiological Action of Drugs. By Charles Wilson Greene, Ph.D., Professor of Physiology and Pharmacology, University of Missouri. Third edition, revised; with 37 new illustrations. Philadelphia: P. Blakiston's Son & Co., 1909.

This little book of less than eighty pages gives an outline of the laboratory experiments necessary for the student in pharmacology. The drugs selected for this purpose are: Alcohol, ether, chloroform, chloral hydrate, the opium series, caffeine, strychnine, cocaine, quinine, atropine and scopolamine, nicotine, curare, pilocarpine, physostigmine, aconite, veratrine, digitalis, ergot, suprarenal gland, nitroglycerin and the nitrites, carbolic acid, potassium, calcium, and barium salts. Under each drug there is given a list of experiments chosen with due consideration to the facility with which they may be performed by students.

A Handbook of Suggestive Therapeutics, Applied Hypnotism, Psychic Science. By Henry S. Munro, M.D., Americus, Georgia. Second Edition. St. Louis: C. V. Mosby, Medical Book and Publishing Company, 1908.

The writer stated in the first edition that his book was intended for the general profession, rather than for neurologists or psychotherapeutists, and as such it was accepted. The first edition was exhausted within a year. It appeared at an opportune time. The profession was being assailed on every hand by inquiries concerning suggestive therapeutics, due largely to popular lectures on moral control of nervous disorders and the practice of various cults on the part of the clergy and other laity. The physician's attempts to direct the "psychic factor in therapeutics" has been practised since the beginning of medicine. It is only of late years that it has become a conscious practice, and the science and art of psychotherapy have been elaborated. Every attempt by the profession to rescue psychotherapy from what the writer styles the "placebo capsule of religious dogma or bonepath massage" should be welcomed. The usefulness of suggestive therapeutics cannot be overestimated. The actual practice of hypnotism, however, could not and should not be done by every practitioner. It is better left in the hands of the few, yet preferably medical men. This second edition of Dr. Munro's book shows a completer index and the addition of some new material. The writer's enthusiasm leads him into advocating psychotherapy in treating at least the mental state in every disease.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles on Treatment, Medicine, Surgery, Neurology, etc., by Leading Members of the Medical Profession Throughout the World. Edited by W. T. Longcope, M.D., Philadelphia, U. S. A. Volume II., Nineteenth Series, 1909. Philadelphia and London: J. B. Lippincott Company, 1909.

This volume of the well-known quarterly consists of twenty articles under the headings treatment, medicine, surgery, gynecology and obstetrics, ophthalmology, otology, proctology, psychiatry, and pathology. In the first article Shoemaker considers the methods and the results of immunization against typhoid fever; Allyn writes a readable article on the treatment of tuberculous serofibrinous pleurisy; Goodman considers the present status of the Cammidge reaction, giving a review of the literature and the results of a personal study of the test; intraocular tumors are considered by Buchanan; two articles on perithelioma of the testis and on the pathogenesis of spontaneous cerebral hemorrhage by Bushnell and Fletcher, and by Ellis close the volume. In the interest of the subjects treated the value of material, and the excellence of illustrations this volume keeps up the high standard set up by its predecessors in the series.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Outdoor Out-Patient Medical Department of the Jefferson Medical College Hospital. June, 1909. Philadelphia and New York: Lea & Febiger, 1909.

The present number contains articles by W. B. Coley, on Hernia; I. G. Clark, on Gynecology; E. M. Foote, on Surgery of the Abdomen Exclusive of Hernia; A. Stengel, on Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Spleen, Thyroid Gland and Lymphatic System; and E. Jackson, on Ophthalmology. Among the sections of more than ordinary interest and value we would specially notice those on Hernia Connected with Undescended Testicle, Pseudoincarceration of Hernia, Cancer of the Uterus, Gonorrhea in the Female, Exophthalmic Goiter and Diabetes. This number contains J. G. Clark's annual review of the cancer problem.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-seventh Annual Meeting, Held at Belfast, July 23—31, 1909.

Special Report to the MEDICAL RECORD.

(*Continued from page 289.*)

SECTION OF MEDICINE.

Friday, July 30—Third Day.

Gastric Illumination.—Drs. THEODORE THOMPSON and H. S. SOUTTAR of London gave this demonstration. After Dr. Souttar had described the instrument, which was of his own making, Dr. Thompson described its sphere of usefulness, at the same time criticising adversely our present methods of the early diagnosis of structural diseases of the somach. By using a nosepiece which rotated the point of the instrument the whole of the gastric mucous membrane could be examined. The principle of the instrument was the production of a very small image of the gastric wall within a rigid tube, which image was looked at with a telescope, a part of the tube admitting of focusing adjustment.

Dr. GORDON GULLAN of Liverpool described an obscure case of hour-glass contraction of the stomach, with special reference to diagnosis.

Treatment of Tic-Douloureux.—Dr. PARVES STEWART of London read a paper on the technique and results of Schlösser's method of treatment of tic-douloureux by the injection of alcohol into the foramen of Exil of one or other branch of the fifth nerve at the floor of the skull or quite close to the gasserian ganglia: the freedom from pain was produced for ten or eleven months at first, and after subsequent injections for longer intervals, and there were no paralyses or deformity. The injections might have to be repeated at first every day or two. Slight transient paresis, edema, or stiffness were the only drawbacks. Of fifteen cases treated, eleven were rendered completely free from attack. The operation was demonstrated on a patient before the section.

Dr. TOM H. WILLIAMS of Washington read a paper on the treatment of tabes dorsalis by antisyphilitic remedies, especially the intravenous or intramuscular injections of mercurial solutions.

Dr. H. D. ROLLESTON of London read a paper on pruritus in lymphadenoma, maintaining that if it occurred in an early stage of the disease the prognosis was unfavorable.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Thursday, July 29—Second Day.

DR. JOHN CAMPBELL IN THE CHAIR.

A Discussion on Endometritis.—Dr. HASTINGS TWEEDY of Dublin, in opening this discussion, said that he made the following divisions of endometritis: Clinically, into acute and chronic; anatomically, into corporeal and cervical. The acute variety was microbic in origin and often went on to chronic. In the treatment of the acute variety (puerperal) he advocated proceeding on general surgical principles, removing dead areas of infection, draining the pools, and endeavoring to increase the bodily resistance. He would give first an intrauterine douche of sterile salt solution with aseptic precautions; if there was any reason to suspect disintegrating material in the uterus he would explore with a gloved hand, but this usually required an anesthetic and the introduction of the whole or half hand into the vagina. He would put in a drain of iodoform gauze soaked in carbolic acid, which he would remove in 24 hours. Before the first douche a specimen was taken for bacteriological examination and the preparation of a vaccine. Anteflexion and retroflexion were dealt with. The blunt curette was occasionally useful when there was danger of rupturing a recently torn perineum if the hand were introduced. The sharp curette was never advisable. In chronic endometritis the symptoms were amenorrhea, dysmenorrhea, menorrhagia, and the passage of casts and clots. The referred symptoms were pain in the back, weakness in the loins, weariness on slight exertion, headache, and dyspepsia. For all these cases the treatment was curetting preceded by dilatation of the cervix, and followed by washing out with a Boyeman's catheter afterwards swabbing with formalin 1 in 3 on a Playfair probe, taking care to boil the probe after putting on the cotton wool. He put in a wick of gauze which he kept in 24 hours. He kept the patient one week in bed. Mild cases might be treated without curetting by swabbing with formalin or injecting iodine; he did not do the latter oftener than once in three months. No operation for repair of the cervix or perineum or for dealing with a displaced uterus should ever be performed without at the same time doing curetting. For cervical endometritis, he advised partial amputation of the cervix, and if that failed to cure then dilatation of the canal and light application of the cautery. Cases of endometritis attended by severe hemorrhage which failed to yield to curetting were best treated by atmocausis, from which he had seen no ill effects.

Professor FEHLING of Strasburg would just separate the cases due to general disease and in these would not use local treatment. He advised wearing a flexible intrauterine tube after curetting. He was opposed to frequent cauterization. In performing curetting he always measured the length of the cavity with the sound fist and let his assistant place a hand on the fundus. He had given up atmocausis. He would not amputate the cervix in a fertile woman; he treated erosion by the sharp spoon.

Dr. ARCHIBALD DONALD of Manchester said the symptoms of endometritis were hemorrhage, leucorrhea, dysmenorrhea, dragging pains in the iliac region, and hypogastrium, and these were relieved by curetting, which must be done thoroughly and carefully. He believed strongly in gauze packing after curettage. In cases of erosion of the cervix he thought that the condition was often due to irritating discharge from the uterus, and he would curette, but in the case of a much thickened cervix he would remove a wedge-shaped piece.

Dr. F. W. KIDD of Dublin had known cases in which too vigorous curetting had been followed by permanent amenorrhea.

Dr. T. J. MCCANN of London combined curetting with modified test case lasting four to six weeks. He used a blunt curette for the body and a sharp one for the cervix, and swabbed out the cervical canal with 50 per cent. chloride of zinc in cases of troublesome cervical discharge.

Dr. THOMAS WILSON of Birmingham considered that the indication for curetting was hemorrhage, and that it was no good for pain or discharge. He found that all cases in which dilators above No. 13 were used presented evidence of laceration of the cervix, if examined by the finger. After curetting he applied strong iodine fortnightly for three months.

Dr. THOMAS CULLEN of Baltimore said that during a period of four years he had all the scrapings which had been removed by the lancette in a large hospital practice examined by a pathologist, and during the whole of that time there were only forty-eight cases in which endometritis was reported. He thought that there was no difficulty in diagnosis from the histological standpoint, but clinically it was often impossible to say if endometritis was present. Vaginal discharge was often due to a weakened

condition of the general health, and disappeared when the latter improved. He used the bladder dilator.

Professor Alfred Smith of Dublin thought that laceration of the cervix was less likely to occur if preliminary dilatation by a tent was used.

Dr. Henry Jellett of Dublin used formaline, had seen cases of occlusion of the cervix after the application of chloride of zinc, and thought it dangerous. In cases of retroflexion he curetted, and if the uterus was fixed performed ventral fixation; if it was movable, Alexander's operation.

Dr. Fred Edge of Birmingham advised hollow dilators to avoid danger of pressing secretion from the uterus into the tubes.

Dr. S. Cameron did not use flushing curette in case perforations should occur, when it would be dangerous.

Dr. Alexander Russell of Glasgow spoke of the importance of sexual rest after curetting and in endometritis.

Dr. T. B. Grimsdale of Liverpool agreed with Dr. Donald that endometritis was the origin of most of the symptoms associated with retroflexion.

Dr. Munro Kerr of Glasgow had also found, as Dr. Cullen, that in many cases regarded as endometritis clinically there was little histological change in the epithelium. Cases in which curetting failed were often really metritic.

Professor Henry Corby of Cork thought that the benefit of gauze packing was that it induced contraction of the uterus.

Dr. E. J. MacLean of Cardiff had found that when packing was used the recovery was not so satisfactory and afebrile.

The President thought that it was impossible to clear out the puerperal uterus by the fingers, and favored the curette.

Professor Tweedy, in reply, said that by passing the hand into the vagina the whole interior of the uterus could be reached.

An Ovarian Tumor, Clinically Malignant, Arising from the Overgrowth of Lutein Cells.—Dr. Smallwood Savage of Birmingham reported this case. The patient was thirty-eight years of age, and had had four children. There had been hemorrhage for seven weeks. She died from exhaustion five and a half months later. The tumor grew from the right ovary, was undoubtedly clinically malignant, and under the microscope showed cells resembling those of the corpus luteum.

Development of the Epithelial Elements of the Ovary.—Dr. Louise McIlroy of Glasgow gave a lantern demonstration of this at a conjoint meeting of the Sections of Anatomy and Obstetrics. She had used the embryo of the puppy, kitten, pig, and human, and considered these better than the rabbit, which was so frequently made use of. She estimated the period of development by measurement. She had found that the so-called Fluger's tubes were really Graafian follicles with a hollow center, due to the ovum being at a different level or having fallen out, and she had found that the cells of the stroma closely resembled those found in chorion epithelioma.

Friday, July 30—Third Day.

Treatment of Contracted Pelvis.—Professor Gehling of Strasburg read this paper. He said that the earliest treatment was the induction of premature labor introduced by Denman. He then alluded to the treatment directed toward reducing the weight of the child, as advised by Prochownik; experiments on animals had confirmed Prochownik's views. It had been proved that the putting on of fat in the fetus took place in the last six to eight weeks of pregnancy, and consequently the restricted diet was of most service then. Another way of causing the fetus to be small was by inducing premature labor; it was most useful in multiparæ, and should be seldom performed at the first labor. He used hydrostatic dilators and sought to obtain a cephalic presentation; he had had children surviving in 76 per cent. of cases. Walcher's position increased the conjugate by 1 to 1.5 cm., and he had used it successfully for the after-coming head. The best means, however, for increasing the conjugate was pubiotomy, which, with a separation between the bones of 4 to 6 centimeters, gave an increase in the conjugate of ½ to 2 cm. For the private practitioner he advised high forceps, and if that failed, craniotomy, and he countenanced perforation of the living child in certain circumstances in the interest of the mother. For performing pubiotomy he chose the subcutaneous method of Doederlein or Bumm, guiding the needle by the finger introduced into the vagina, and he awaited spontaneous labor after dividing the bone. He tamponed the vagina for twenty-four hours and kept in a self-retaining catheter for forty-eight hours. His maternal mortality had been 3.2 per cent.; fetal, 9.6. He preferred pubiotomy to symphyseotomy, as he had found that the latter gave rise to more bleeding and was more liable to be followed by damage to urethra or bladder. He then described the newer method of extra peritoneal cesarean section, and said that it presented advantages in cases already infected; it must be done when the cervix was well stretched, and not at the beginning of labor; if the peritoneum was accidentally opened it could be closed by suture and no harm resulted.

Professor Murdoch Cameron of Glasgow said that pubiotomy caused permanent lameness, and he preferred induction of labor by bougies.

Dr. Munro Kerr of Glasgow had not found the results of induction of labor satisfactory, and he disapproved of high forceps, his experience being that it resulted in 50 per cent. of still-births. He laid stress on the great importance of giving nature as much time as possible, and even with a conjugate of three inches he had seen spontaneous delivery. He though pubiotomy was indicated after one thorough effort with forceps had not succeeded. Pubiotomy was very undesirable in primiparæ.

Professor Tweedy of Dublin said that the pelvis was often inaccurately measured, and the only reliable method was by Skutsch's pelvimeter. This proceeding required an anesthetic; he did not measure the pelvis in primigravidæ until full term of labor. We should act when the fetal heart quickened, and not wait for the subsequent flowing, as by the time that occurred it would usually be too late to obtain a live child. Perforation of the living child should never be done in a lying-in hospital, but was still occasionally unavoidable in private practice.

Professor Fehling, in reply, said that he found that the patients could walk perfectly well after pubiotomy, even when there was no bony union. He measured the pelvis with the fingers under an anesthetic.

Dystocia Due to Central Fixation of the Uterus.—Professor Murdoch Cameron of Glasgow reported two cases, in each of which the os was out of reach until the whole hand had been introduced into the vagina; in each one he found it necessary to perform embryotomy. He said that in every case in which ventral fixation was performed the patient should be sterilized by tying and dividing the tubes.

Professor Jacobs of Brussels considered ventral fixation an extremely dangerous operation; he had seen three fatal case of ileus from strangulation of intestine by the fixation band.

Dr. T. J. McCann of London advised that fixation should be done low down on the anterior wall of the uterus.

The meeting then joined the Opthalmological Section for the consideration of the report of the Ophthalmia Neonatorum Committee.

SECTION OF SURGERY.

Wednesday, July 28—First Day.

The President, Professor Thomas Sinclair, opened the proceedings by reading a short introductory address to the members.

The Operative Treatment of Obstructive Jaundice and the Proper Selection of Cases.—Mr. B. G. A. Moynihan of Leeds opened this discussion. He laid stress on the extreme difficulty, almost amounting to impossibility, of making a correct diagnosis of the actual pathological condition in many cases of obstructive jaundice either by clinical or chemical examination. Investigation should be conducted along three main lines: (1) clinical history, (2) physical signs, and (3) examination of the urine and feces. With regard to (1), the anamnesis exhibited by painstaking inquiry of the patient elicited results of high value as to the inaugural symptoms, and indicated the localization and character of biliary and other abdominal diseases. The history disclosed two types of obstructive jaundice. In the first type the onset was painless and insidious, jaundice being noticed by outsiders before the patient was aware of anything being wrong. Icterus deepened by slow degrees until a greenish-black coloration of the skin was reached; there was no pause in the stealthy onward march, each week finding the tint deeper than before. Simultaneously there was impairment of general health, malaise, increasing loss of appetite and emaciation. Here there was progressive obstruction of the common duct from some cause either within or without the duct, and that cause was nearly always malignant disease, beginning, it might be, in the hepatic duct at the junction of the three bile ducts, in the common duct, in the ampulla of Vater, or in the head of the pancreas; the last situation being far and away the most frequently met with. Exceptionally a stricture of the common duct might be the cause. In the second type there was initial pain, then faint jaundice which deepened quickly, but never reaching the dark color of the first type, the tint being yellow or orange rather than green. Then something happened—increase of pain, or pyrexia or rigors, followed by defervescence of symptoms for a time and then recurrence. The symptoms ebbed and flowed. Here there was generally a foreign body in the hepatic or common duct, almost always a gallstone, but he had known a hydatid cyst to become impacted in the duct. Chronic pancreatitis accounted for some of these cases, but far less frequently than stone. With regard to (2) *i. e.* physical signs, the gall-bladder might be distended or contracted. Courvoisier's monumental work had established that obstructive jaundice with contraction of the gall-bladder was due to stone, while obstructive jaundice with dilatation of the gall-bladder was due to a cause other than stone. This almost amounted to a law, though there were exceptions, *ex. gr.* dilatation associated with cholecystitis, or a stone in the cystic duct. In his experience malignant disease in the head of the pancreas was not palpable through the abdominal wall. Ascites was a valuable physical sign. He cited a rare case of stone in the cystic duct causing both ascites and jaundice by pressure in the portal vein and hepatic duct. With regard to the third line of investigation—examination of the urine and feces, he was satisfied that Dr. Cammidge had made good his claims on this subject, especially in respect of the crystals found in the urine when pancreatitis was present. He mentioned a case in which he diagnosed malignant disease of the head of the pancreas (green jaundice, a distended gall-bladder, and petechial hemorrhages comprising the chief data), whereas Dr. Helen Stewart's report on the patient's urine and feces negatived his diagnosis and indicated an obstruction above the ampulla of Vater. Operation disclosed a duodenal ulcer causing occlusion of the common bile duct; cholecystenterostomy was performed and the patient cured. Referring to calcium chloride, he regarded this drug as worthless for increasing the coagulability of the blood, and thus opposing hemorrhage in operations for jaundice. Crile had suggested an alien serum. Mr. Moynihan had tried this on a "bleeder," using diphtheria antitoxin from a horse with complete success, though previous treatment with gelatine and sugar had failed to arrest the bleeding. He now used a sterile serum from a rabbit, as advised by Munro, and had met with no failure so far.

Removal of cancer of the head of the pancreas was inadvisable, the experience of Murphy and himself showing a mortality of eighty per cent.; but great relief from the intolerable itching of the skin in such cases was gained by cholecystenterostomy. The operation should be done under local anesthesia with a substance such as novocaine; infection was likely to follow if the colon was anastomosed with the gall-bladder, and the junction should therefore be made with the duodenum high up, or even with the stomach. He did not approve of removal of the gall-bladder in obstructive jaundice. Finally, on rare occasions an exploratory operation might be necessary. It should then be done with scrupulous care as to asepsis, after the injection of alien serum, and under local anesthesia. Only one finger should be inserted through the abdominal wall with an irreducible minimum of disturbance.

Sir Thomas Myles of Dublin continued the discussion. He dwelt on the imperative necessity of careful and prolonged examination before deciding on an operation for obstructive jaundice. In 1886 he performed the first successful operation in Ireland for this condition; the distended gall-bladder was drained after evacuation of twenty-eight stones. As to diagnosis, the difficulties were so great that it was not possible to forecast what one would encounter in obstructive jaundice. He deprecated speaking of a clinical law; it was easy to remember a so-called law, but not so easy to remember the numerous variations and exceptions. Though paradoxical, it was not going too far to say that the larger a gall-bladder the more difficult was its diagnosis. He cited a case where the gall-bladder looked like a length of bowel reaching down to the pelvix and containing about a hundred calculi. He eulogized the work of Cammidge, and insisted on careful investigation of the urine, feces, and blood in a clinical laboratory. Referring to operative treatment he thought that removal of the gall-bladder was seldom justifiable; one reason being that drainage of the ducts, which was often highly beneficial, was thereby prevented. He mentioned a case of chronic pancreatitis greatly relieved by posterior gastrojejunostomy after drainage of the gall-bladder had failed to benefit.

Mr. C. P. Childe of Southsea held that more attention should be paid to the preventive treatment of jaundice due to gallstones. When their presence in the gall-bladder was ascertained calculi should be removed before they passed into the ducts or caused later dangers. Whereas the mortality of cholecystotomy was practically nil, at least five per cent. of choledochotomies were fatal. He mentioned cases illustrating certain risks menacing patients with gallstones, including local cancer, gangrene, and rupture of the gall-bladder, ulceration of calculi into the bowel giving rise to obstruction, and cholangitis. In his opinion calcium chloride was of no service in preventing hemorrhage in obstructive jaundice.

Dr. J. Crawford Renton of Glasgow advocated the use of radiography for the detection of gallstone when their presence was suspected in the absence of unequivocal symptoms. He agreed that the diagnosis of enlarged gall-bladder was often difficult, citing a case where the fundus extended to the right iliac region, unassociated with pain or jaundice. Green jaundice was not always due to

malignant disease; he mentioned three cases of this kind in which recovery followed drainage.

Mr. Stanmore Bishop of Manchester was impressed by the value of Murphy's method of examination for gall-stones. He had found calcium chloride useful when given in large doses before operation—thirty grains three times a day by the mouth, and in addition thirty to fifty grains by the rectum. For the cure of biliary fistula by cholecystenterostomy he insisted that the anastomosis must be made with the duodenum; he had twice effected junction with the colon, but both cases were fatal, owing to the passage of feces into the gall-bladder, and in one instance feces had reached the liver.

Mr. W. I. de C. Wheeler of Dublin urged that obstructive jaundice should be prevented by close attention to the early symptoms of cholelithiasis. Cammidge's method, though of great value, was too elaborate for common use. Iodiform given by the mouth in gelatine capsules yielded iodine in the urine when chronic pancreatitis was absent, and *vice versa*. Mayo Robson's test—the reaction of the feces to litmus—was unreliable. Gallstones were not inoffensive foreign bodies and their removal would anticipate secondary lesions. He cited a case of a large gall-bladder adherent to the colon and causing intestinal obstruction which had been diagnosed as carcinoma coli; and another case in which prolonged drainage of the gall-bladder had been successful treatment for chronic pancreatitis.

Mr. A. B. Mitchell of Belfast said that chemical investigation of biliary diseases should be encouraged and due remuneration provided for competent workers. He referred to a case of cancer of the head of the pancreas in a girl of sixteen with enlarged gall-bladder, jaundice, and intermittent pyrexia. He had found calcium chloride useful when given in large doses—twenty grains every two hours.

Professor Sonnenberg of Berlin described a case of acute yellow atrophy of the liver following appendectomy.

Mr. McAdam Eccles of London supported the views of others as to the value of Cammidge's method, the use of *x*-rays, and the administration of calcium chloride in large doses.

Mr. Moynihan in reply said that calcium chloride did not alter the coagulation time of the blood in jaundice, and was worthless. He agreed that obstructive jaundice due to calculi ought to be prevented; surgeons must detect and deal with the inaugural symptoms of cholelithiasis. In obstruction of the common duct, jaundice was absent in one-third of the cases. He advised that the surgeon should exhaust his own investigations before hurriedly resorting to radiography for a diagnosis.

Some Cases of Resection of Intestine.—Mr. G. P. Newbolt of Liverpool read this paper. His first five operations were done for gangrene in strangulated hernia. Murphy's button was used, and four of the five were successful. He now employed no appliance, and usually made end-to-end junction, the herniotomy wound being extended upward, thus avoiding a separate incision into the abdomen. In cases of new growth he preferred a median section below the umbilicus. He also favored end-to-end junction in resection of the colon, special care being observed at the mesocolic border; when there was plenty of gut to allow of overlapping, he made side-to-side junction. In cases of obstruction other than those due to strangulated hernia, he regarded a preliminary drainage of intestine essential to success.

Sir Thomas Myles of Dublin, while congratulating Mr. Newbolt on his successes, thought immediate resection of gangrenous strangulated bowel a hazardous procedure. His own practice was to relieve the strangulation, and then wait about six days before resecting. He also preferred side-to-side anastomosis rather than end-to-end.

Mr. McAdam Eccles of London supported the practice of immediate resection of strangulated bowel. He approached the hernia through a separate incision, and drained the original hernial wound.

Mr. G. A. Syme of Melbourne was against resection of intestine in a hernial sac, and advocated a separate incision for the purpose. He also regarded side-to-side anastomosis as safer than end-to-end.

Mr. A. B. Mitchell of Belfast mentioned a case in which he had successfully resected about twelve feet of bowel.

Mr. C. P. Childe of Southsea referred to a series of seven cases of resection of gut for gangrenous hernia in which he had operated with six recoveries. He effected lateral anastomosis, and did not make a separate abdominal incision.

Mr. Thelwall Thomas of Liverpool thought it safer to operate in two stages for gangrenous strangulation, because of the coexisting septic cellulitis around the hernia. In the first stage, after relieving the obstruction, he secured the limbs of the loop of bowel by stitching them to the edges of the wound. He regarded this as an important step, as there was risk of unsecured gut slipping back into the abdomen.

Thursday, July 29—Second Day.

Differential Treatment of Tuberculous Joints.—Sir William Macewen of Glasgow, in opening the discussion, said that exact determination of the pathological phenomena of a diseased joint must precede treatment, because treatment necessarily varied with the pathology, and, in the case of tubercle, with the stage of the morbid process. In the early or gray stage, while the blood supply is still good and active phagocytosis is going on, treatment may be effective through the blood stream and by direct local measures; but in the stage of caseation and tissue necrosis the former agency was of little use, and recourse must be had to operative removal or the application of chemicals. In view of the secondary effects of joint-tubercle operation should not be too long delayed; and it would be more successful if performed before the capsule of the joint was destroyed. When the disease is recent and limited to bone, as in the epiphysitis of children, operative treatment is decidedly good; but the risk of general tuberculosis must not be forgotten. He advocated operation in two stages—first, making a route through the synovial membrane to be scaled off from the cavity of the joint; and then, after an interval, reaching the disease by a tunnel in the bone, stopping short of the articular cartilage. In the gray stage he injected sterilized iodoform emulsion, taking care to continue injecting all the way out, a few drops of emulsion thus escaping as the needle was withdrawn; but he preferred to have the route shut off beforehand. Failure to recognize the difference between the gray and caseating stages had induced some surgeons to give up the use of iodoform emulsion, since, in the latter stage with diminished phagocytosis, the benefit was much less, and removal of the diseased joint gave a speedier result. But even caseated bone underwent absorption in response to stimulation of the surrounding tissues by iodoform. The injection of subnitrate of bismuth, first used for the purpose of radiography, was also serviceable in treatment. In this connection he pointed out that iodoform, by its *x*-ray shadow, enabled the surgeon to track the tortuosity of a sinus. Bier's method of congestion was good, and its results were still better when combined with the use of iodoform. He also approved of massage, especially when the synovial membrane was affected. In the later, necrotic, stage of tubercle, removal by operation was indicated. He filled the gap in the bone with iodoform in large scales, or mixed with boric acid: toxic effects, common enough when finely powdered iodoform is used, very

seldom occurred, because its absorption was slow, and it could be seen *in situ* by the *x*-rays several years after insertion. Along with operation he advised rest and fixation of the diseased joint. In the final stage, when the articular cartilage has been shed, the question of excision, or possibly amputation, must be considered, even in the case of young children. But excision should be limited to the area of disease, and not done as advised in some text-books; moreover, special care should be taken to avoid arrest of growth in the long bones of children.

Mr. Robert Jones of Liverpool continued the discussion. He remarked on the difference between children and adults in respect of tuberculous joints, and said he seldom excised in the young, often in adults. As tuberculosis in childhood was simulated by other pathological conditions, he differentiated by injecting three to five milligrams of Koch's tuberculin between the shoulder-blades under antiseptic precautions. Radiography was of small value in the diagnosis of early bone tubercle, and so, too, was pain, because of its inconstancy. The most trustworthy sign of arthritis was rigidity; it was of early onset and tended to limit movement in every direction. In the treatment of tuberculous joints in children the greatest reliance must be placed on rest, fresh air, and food. Rest was best secured by a suitable appliance—as a rule without traction. With regard to the posture of various joints, the hip should be extended and abducted, the knee extended, the elbow flexed, the wrist hyperextended, the ankle dorsiflexed so that the heel would be the first point to impinge on the ground, and the spine overextended on a convex surface. Fresh air was of vital importance, and the maximum amount of good was obtained by those patients who were supplied with the maximum amount of fresh air. He declined to treat cases of tuberculous joints in children within the wards of a town hospital; he considered they did better in the slums, and he believed the days of town hospitals for tuberculosis were numbered. The diet should be on a generous scale, all kinds of appetizing and nourishing foodstuffs being supplied, and the children encouraged to eat. For tuberculous abscess he had tried many forms of treatment, but now adopted a conservative attitude, and in many cases awaited events on the lines of expectancy. In his view the tubercle bacillus was not pyogenic. Cold abscesses not infrequently became absorbed without any untoward clinical sign. When absorption did not ensue, he allowed the abscess to travel toward the surface, and then, with scrupulous precautions, evacuated it through a small incision, avoiding the use both of irrigation and the curetting spoon. If the abscess was associated with pyrexia, he opened it and attacked the diseased bone. A retropharyngeal abscess always needed early evacuation through an incision behind the sternomastoid muscle. He was opposed to operation for pressure paraplegia, preferring the overextension of the spine, and he had known recovery follow after four years of this treatment. He recommended a boiled mixture of bismuth subnitrate one part, vaseline, two parts both for diagnosis and treatment; he had also used with advantage a bismuth paste composed of the subnitrate, white wax, and vaseline Immunization by opsonins was too recent to justify an exact estimate of its value, but the outlook was hopeful. Lastly, he agreed with Sir W. Macewen as to the usefulness of passive movements and Bier's method.

Prof. Sonnenberg of Berlin gave details of the treatment and cure of tuberculous joints by repeated injections of Robert Koch's tuberculin. The effect was tested every third week by von Pirquet's inoculation.

W. Arthur Tubby of London contributed a paper which was read by the honorary secretary. He referred to cases of extraarticular origin with subsequent invasion of the joint, and pointed out that in juxta-epiphyseal tubercle, the liability to rapid invasion varied with the relation of the epiphyseal line to the different joints. He drew particular attention to paraarticular tuberculosis of bone. Its onset was insidious; there was constant recurrence of pain in one spot, which was acutely painful on pressure, and where thickening could be felt. Muscular paresis followed; and, though the movements of the adjacent joint were tolerably free, movement in one direction, varying in different cases, always elicited pain. The *x*-rays revealed a tuberculous focus. The disease was apt to light up in an adult after years of quiescence. Syphilis of bone could be discriminated by its nocturnal pain, and by its tendency to involve the shaft rather than the epiphysis. If treatment by rest and counter irritation proved unsuccessful, the diseased area should be excised and cauterized with zinc chloride.

Mr. J. Crawford Renton of Glasgow regarded early diagnosis as imperative, and he found assistance in the *x*-rays and Calmette's method. For treatment he advised Bier's passive congestion, Wright's opsonins, fresh air, and rest. In neglected cases of advanced joint disease, excision was required, followed by careful after-treatment. To prevent bending of the excised knee, he encased the limb for eighteen months in a plaster-of-paris splint.

Mr. J. Ward Cousins of Portsmouth advocated prolonged treatment by rest, deferring operation as long as possible.

Mr. Maynard Smith of London read a paper on the "Inoculation Treatment of Tuberculous Arthritis." He was convinced, by personal investigation of the cases treated in a London Children's Hospital during two years, that the results obtained by the methods in vogue before the introduction of vaccine thereby were unsatisfactory. The administration of tuberculin in dependence on the opsonic index marked a distinct advance, and was applicable not only in the way of treatment, but also for diagnosis, and for determining when cure could be predicted. He presented a table showing particulars of thirty-four cases treated at St. Mary's Hospital by inoculation. Of these, five were treated by inoculation alone, four making complete recoveries, and the fifth was cured with some deformity remaining. In twelve cases previous treatment by splinting, rest, or operation had proved unsatisfactory; by inoculations eleven were cured (eleven cases with complete restoration of function), and the twelfth case was improving under treatment. Of the remaining seventeen cases, nine were cured with partial restoration of function, four were improving, and four were not improved up to the present. He also presented a table of cases to prove the possibility of determining by inoculation whether or not a cure has been effected.

Mr. Rushton Parker of Liverpool spoke of the debt of gratitude due to Hugh Owen Thomas for the introduction of his splint in 1874.

Mr. C. W. Cathcart of Edinburgh claimed that Bier's treatment was of great value, and it had the merit of simplicity. He was strongly in favor of injecting iodoform emulsion into tuberculous abscesses and joints; sterilization was not required if the ingredients were mixed in the proportions of iodoform one part, glycerine nine parts. Immense benefit accrued from the administration of tuberculin, but the estimation of the opsonic index required a good deal of time. Excision was necessary in many cases as the lesser of two evils.

Sir William Macewen, in replying, spoke favorably of Calmette's test for tuberculosis. He laid stress on tenderness as an early sign to be elicited by methodical palpation with a finger. In conclusion he showed a large series of photographs displaying the excellent functional results following the limited excisions he had previously described.

Friday, July 30—Third Day.

Some Unusual Cases of Echinococcus (Hydatid) Cyst.—Mr. G. A. Syme of Melbourne, Australia, read this paper. He related several rare cases of echinococcus in the ilium, sacrum, and spine. When the parasite invaded bone, exogenous reproduction in the cancellous tissue occurred. In the lung, daughter cysts were unusual, and in bone common. Unruptured and uncomplicated hydatid cysts in the liver or lung showed a typical shadow in a radiograph. A liver cyst might discharge part of its contents into the hepatic duct, thus giving rise to symptoms of obstructive jaundice resembling those caused by gallstones; but much more frequently rupture took place through the diaphragm into the lung. The value of the precipitin reaction in the diagnosis of echinococcus was not finally settled. In his own observations at Melbourne he had not obtained any reaction between hydatid fluid and serum from hydatid patients. Observers in the Sydney hospital had met with varying results, some positive and some negative. He thought some aid in diagnosis might be furnished by the eosinophile corpuscles. With regard to treatment he advised removal, by enucleation when possible, and, failing that, by marsupialization. It was imperative that none of the cyst contents should be allowed to get into the peritoneum or the tissues opened up by the operation wound. If a hydatid of the liver had invaded the lung, it should be approached through the abdomen. A suppurating cyst required incision and drainage. Amputation must be resorted to when extensive damage had been inflicted by cysts in a long bone.

Enucleation of the Prostate.—Mr. P. J. Freyer of London read a paper entitled: "A recent series of 200 cases of Enucleation of the Enlarged Prostate, with special reference to the operation (1) in octogenarians, (2) in cases of extremely large prostate." He also exhibited a series of prostates removed by operation, the weight varying between half an ounce and seventeen ounces. Several cases in groups (1) and (2) were described in detail. Fifty-seven patients were in their eightieth year or upwards, the oldest being 89; of these fifty-one recovered and six died. Experience led him to the conclusion that the chance of successful enucleation was as good in the aged as in younger men, premising that the vital organs, and especially the kidneys, were sound. Altogether he had performed the operation on 644 patients, of whom thirty-nine died, *i.e.* a mortality of 6 per cent. The average age was 69 years, and the average weight of the gland two-and-a-half ounces. In 114 cases vesical calculus was present. He strongly recommended the practice of preliminary suprapubic drainage of the bladder for some days before attempting enucleation in patients exhausted by toxemia, pain, suppuration, and pyrexia due to cystitis and foul urine.

The Diagnosis of Malignant Disease by Estimation of the Antitryptic Content of the Blood Serum.—Dr. E. C. Hort of London read a paper with this title, of which the conclusions were the following: "(*a*) A normal antitryptic power appears to be of great service in excluding a diagnosis of malignant disease. (*b*) A raised antitryptic power occurs in many autoinfections (non-malignant), in many bacterial infections, and in 94 per cent. of 100 cases of cancer. Hence a raised content is no proof of malignancy, but is often of great value in establishing a positive diagnosis, in the absence of simple autoinfection and of bacterial infection. (*c*) A raised antitryptic power appears to be often of great value in distinguishing innocent growths from malignant, as, for example, chronic mastitis from cancer of the breast, and simple gastric ulcer from cancer of the stomach. Apart from the diagnostic value of these observations it appears that the fact that the antitryptic power of a cancerous serum is generally high throws some light on the autoinfective nature of the cancerous process on acount of the same phenomenon occurring in simple autoinfections and in bacterial diseases. Further, it indicates the necessity for studying the factors that produce a rise in antitryptic and other antiferment content, such as the intracellular enzymes and co-enzymes, and the products of morbid cell activity, before the cure of cancer, by the establishment of immunity, can reasonably be looked for."

Perforating Duodenal Ulcer.—Mr. A. B. Mitchell of Belfast read this paper and gave a summary of the sixteen cases on which he had operated without a death. He remarked on the frequency of duodenal ulcer as indicated by the fact of thirty-two cases of perforation having been admitted into the Royal Victoria Hospital, Belfast, in the space of five or six years. Four of the patients were not operated on, as they were obviously moribund. Of the twenty-eight cases of operation only three died, two of these occurring before the use of continuous rectal perfusion had become routine. He commented on the insignificance of shock in perforated duodenal ulcer, the condition being often absent; and he submitted that the term should be abolished in relation to this class of case. Pain and peritoneal tenderness were constant features, and, above all, rigidity of the abdominal wall; this last sign was a trumpet call for help. Leakage was usually scanty, owing to spasmodic closure of the pylorus. Opium must on no account be given, because it unlocked the musculature and so encouraged extravasation through the perforation. Immediate operation was the only hopeful treatment. Incision was made through the right rectus, and the hole in the duodenum rapidly closed by a purse-string suture. The abdomen was sponged out toward the right kidney, downward along the course of the ascending colon, and within the pelvic basin. Flushing the peritoneal cavity was inadvisable, and it was better to cleanse too little than too much, since the escaped fluid was not very noxious. The pelvis invariably should be drained through a suprapubic opening. Local drainage in the region of the ulcer was not always necessary; when desirable, a rubber tube carrying a gauze wick might be inserted. The after treatment was of vital importance, especially in regard to the two essential items of the sitting posture and continuous saline perfusion by the rectum at the rate of one pint an hour. Altogether, he had operated on sixteen cases, all of whom recovered; in four of these cases he had combined gastrojejunostomy with closure of the duodenal perforation, and in two instances he had performed gastrojejunostomy after an interval respectively of eight days and sixteen months, with complete success.

Intestinal Anastomosis.—Mr. G. H. Edington of Glasgow read this paper, in which he described a series of ten operations with one death, the fatal case being one of gangrenous strangulated femoral hernia in a woman aged fifty-seven. The cases were distributed in three groups, as follows: *Group A:* Enteroenterostomy; four cases of resection of small intestine, comprising two cases of strangulated hernia, one case of gunshot wound, and one case of traumatic rupture. *Group B:* Ileocolostomy; five cases of cecal obstruction, four being due to irremovable carcinoma cæci. *Group C:* Colocolostomy; one case of union of the transverse colon with the descending colon for obstruction at the splenic flexure.

Scopolamine-Morphine Narcosis.—Mr. C. Leedham Green of Birmingham read a paper on this subject. He claimed that the method had great advantages from the patient's point of view. It lessened nervous tension before an impending operation; the patient was already drowsy when the time came for giving a general anesthetic; the amount of anesthetic required was reduced by one-half; there was no sudden fall from full anesthesia

to partial; there was far less mucus secreted in the air passages, thus greatly lessening the risk of post-operative pneumonia; the operation was followed by sound sleep, lasting four or more hours; there was comparative absence of vomiting, and distinctly increased safety. His procedure was as follows: On the evening before operation sleep was secured by ten grains of veronal; two hours before operation a subcutaneous injection of morphine, one-sixth of a grain, and scopolamine, one-one hundred and thirtieth of a grain, was given; one hour later, if necessary, half the foregoing injection was repeated; at the operation ether was administered.

AMERICAN SURGICAL ASSOCIATION

Annual Meeting Held at Philadelphia June 3, 4 and 5, 1909

THE PRESIDENT, DR. C. B. G. DE NANCREDE, OF ANN ARBOR, IN THE CHAIR.

(*Continued from page 294.*)

Excision of the Larynx for Malignant Disease.—Dr. JAMES BELL of Montreal reported 12 laryngectomies. In his experience partial operations on the larynx were not satisfactory. Excision of the larynx was a safe operative procedure. In 7 of the 12 cases operations were done for intrinsic, far advanced cancer of the larynx; in 5 for primary disease of the organ. Of the 12 cases operated on, 7 recovered.

Dr. W. W. KEEN of Philadelphia in 1898 selected as the subject of his presidential address "Total Laryngectomy," and in it he reported a case of excision of the larynx. The man was now perfectly well, it being eleven years since the operation was done. He recommended at that time that the patient be kept in the Trendelenburg position to prevent aspiration pneumonia.

Dr. GEORGE E. BREWER of New York said that the dangers of the operation of excision of the larynx were (1) Aspiration pneumonia; (2) extension of the infection downward along the muscular and fascial planes of the neck toward the mediastinum; (3) too long deprivation of food in old people who were in a bad general state. He believed in early feeding. He introduced a nasal tube into the lower part of the esophagus, and began feeding as soon as the patient came out of the ether. He began the use of water in about six hours after operation and gave eggnogs and concentrated food from the start.

Dr. ROSWELL PARK of Buffalo said that his first laryngectomy was done about twenty four years ago, and the patient nearly died of iodoform poisoning. He was afraid to use iodoform after that, and in a later case employed subnitrate of bismuth. This patient died. An autopsy was made, and he found the lining of every bronchial tube smeared with bismuth that had formed a paste, so that the patient died of asphyxiation from the bismuth.

Dr. N. B. CARSON of St. Louis, after detailing five cases in which he had resorted to laryngectomy, said that rectal anesthesia added very much to the comfort of these patients.

Dr. GEORGE W. CRILE of Cleveland wished to report twenty total laryngectomies. There were two immediate fatalities in the first eight, but none in the last twelve. The ultimate results were quite unsatisfactory. The oldest case was living between fifteen and sixteen years after operation; another five years after operation; one was alive four years after operation; one after three years, and the remainder had been operated on too recently to be considered at this time.

Further Observations on Transfusion, with a Note on Hemolysis.—Dr. GEORGE W. CRILE of Cleveland, Ohio, said that in pernicious anemia, toxemia, leukemia, Hodgkins' disease, carcinoma, uremia, etc., no benefit had occurred from transfusion. No cases of hyperthyroidism were improved apparently by transfusion. In a case of pellagra rapid convalescence was noted after transfusion from an immune donor. In suitable cases it was of great value in the prevention and relief of the circulatory phenomena of shock. They were encouraged by the results of transfusion in pulmonary tuberculosis. As influencing operative surgery, their further experience amply confirmed the earlier observations of the value, in grave surgical risks, of preliminary and post-operative transfusion. There were two notable groups susceptible to results in contemporaneous transfusion, namely, those in which there had been internal hemorrhage, grave or continuous, demanding immediate operation, and those in which the patients were reduced by long continued disease, by starvation, or otherwise to such a degree as to render them unsafe for the operation required. In those cases the donor was attached and a sufficient amount of blood was transferred until the recipient was sufficiently restored to take the anesthetic. All preparations having been made, the patient was then anesthetized, and in the course of the operation the needed amount of blood was transferred from time to time by the assistant in charge at the direction of the operating surgeon. At the close of the operation a sufficient additional amount of blood was transferred to insure the post operative safety of the circulation. As to hemolysis, it must be considered, first, as but one form of manifestation of the end action between the blood of one individual against the blood of another. Second, if there was hemolysis *in vitro*, it by no means necessarily followed that there would be hemolysis *in vivo*. Their agreement might be an exception. Hemolysis was a valuable aid in the diagnosis of active reaction against tuberculosis, occurring more frequently than in carcinoma. In cancer the reaction was largely dependent upon the stage of the disease at the time of observation. Hemolysis usually occurred in the early stages of cancer, and rarely in its late stages.

The Preservation of Dissections of Surgical Anatomy with Permanent Color of Muscles, Vessels, Nerves, and Organs, by a New Method.—Dr. EDMOND SOUCHON of New Orleans, La., in a paper with this title, said that the details of this experimental work, extending over several years, were published in the *Journal of the American Medical Association* on August 22, 1908, and he wished to recall only the most salient features of this new method. The basic condition was a proper embalming formula which would assure color. The aim was not so much to obtain the real color of the living, as that color varied in the various subjects, but to secure a marked contrast between the fleshy parts of muscles and the tendons, bones, and other white tissues, doing away with the uniform bleached appearance presented by so many otherwise beautiful preparations seen in the museums in this country and abroad. After a number of trials, consuming over forty subjects, he had found that so far the following formula was the one that gave the best results for this work. Arsenic, 2½ gallons; formalin, 6 ounces, alcohol, 16 ounces; carbolic acid, 6 ounces; glycerine, 16 ounces, and creosote, 2 ounces. Very lean subjects should be used. A feature of some importance was to allow the parts to be dissected to drain for ten to fifteen days before dissecting them. Otherwise the dissecting was rendered unsatisfactory by the infiltration of the tissues with the embalming fluid. After the dissection was completed, it was placed in a glass jar filled with a solution of carbolic acid, one ounce to the gallon. This was changed as often as it was discolored by the blood. The next important point was the placing of the dissected parts in an empty jar without solution of any kind, but covered with a lid. He called this stage the curing process. It was second in im-

portance to the embalming solution, as it developed or brought out again the color without darkening the tendons or other white tissues. It also smoothed the surfaces, which might be shreddy or ragged; it sharpened the edges of the muscles, thus giving better definition. It fixed the color so as to keep it from being perceptibly affected when the specimen was finally put up permanently in a weak solution of alcohol, twenty ounces to the gallon of water. The arteries and veins must be painted with moist water colors, as coloring matter used in the injecting material would not show when the preparations were preserved in solutions. All solutions should be changed as soon as they became the least cloudy or discolored. This was essential to the permanent beauty. Otherwise the impurities in the cloudy or discolored solutions would settle on the white tissues, stain them, and destroy their whiteness and brilliancy. Some specimens were refractory in developing color. He estimated so far that 85 or 90 per cent. of the specimens turned out satisfactorily. The remainder were merely good, but not good enough to be placed in a museum, especially with one's name attached. That uniformity of color and results did not invariably follow uniformity of procedures was due, he believed, to the fact that the chemical composition of the tissues varied with the subjects. The great practical value of this new method was to give us the means of building study museums composed only of real dissections placed in very large glass jars, in spacious rooms flooded with light, on tables, so that students could come close to and study them. Thus the students could prepare for the dissecting room. They were assisted in their dissections by referring to the preparations in the museum. Their work in the dissecting room was completed by showing them the great number of things which they never saw in a dissecting room. They were also able to review and fix in their minds what they had really dissected themselves. Practitioners could in a few moments relearn much anatomy. Such was the study museum he was now building for the Medical Department of Tulane University in New Orleans. The museum contained 400 very large glass jars with dissections. He had now 200 good ones, and there were 200 to be made over, because they could now be made better, owing to the improvements in the methods. It would take about two or three years to make over those 200.

Thoracic Surgery.—Professor Friedrick of Marburg, Germany, reported eleven cases of unilateral phthisis in which he had resorted to extensive multiple resection of ribs. In two cases of multiple tuberculosis he performed total pleuropneumolysis, and in four partial pleuropneumolysis. He had not lost a single case from this operation.

Dr. Wm. S. Halsted of Baltimore detailed some experimental studies he had made with reference to lung surgery.

Dr. Charles A. Powers of Denver discussed surgical measures designed to relieve pulmonary tuberculosis.

Dr. Leonard Freeman of Denver said that collapse of the lung might be obtained in several ways: (*a*) By the production of artificial pneumothorax according to the methods of Murphy and others; (*b*) by extrapleural resection of the ribs below the first part of the cartilages to the spine, including the periosteum; (*c*) by removal of portions of some ribs, with periosteum along the axillary line; (*d*) by resections of portions of several ribs and periosteum directly over the diseased part of the lung, usually a cavity near the apex; and (*e*) by a similar operation, without removal of the periosteum, followed by external pressure by means of a truss. He described an operation which he had done in two cases, with encouraging results.

Dr. A. Vander Veer of Albany said that the hypodermic syringe, with long needle, was of value for exploratory purposes and a safe instrument for a good general practitioner to use when in doubt as to the nature of the lesion that was present. Repeated use of the aspirator was not to be condemned so long as the fluid remained sterile, and was the preferable method of treatment in malignant cases. Where we had malignant disease in which the effusion was distressing to the patient, the use of the aspirator afforded great relief. The use of the trocar and drainage tube was advisable if it was shown the aspirator was no longer affording benefit. Resection of the ribs was necessary when no improvement took place with the ordinary drainage tube. The latter operation should be done early in order to protect the lungs from unnecessary pressure and relieve adhesions which, in the young, became so detrimental in causing spinal curvature.

Dr. C. L. Gibson of New York reported an interesting case of tuberculous pericarditis in which he succeeded in effecting a cure by means of incision and drainage.

Treatment of Fistulæ and Abscesses Following Operations for Empyema of the Thorax.—Dr. A. J. Ochsner of Chicago in this paper illustrated the value of the injection of Beck's paste into persistent sinuses and abscesses following operations for empyema of the thorax. A tabulated list of fourteen cases treated by the author by this method was given in the paper. Two formulas were in use: No. 1, consisting of one part of arsenic-free subnitrate of bismuth and two parts of sterile amber vaseline, had a lower melting point than No. 2, which consisted of 30 parts of subnitrate of bismuth, 60 parts of amber vaseline, and 10 parts of paraffin of a sufficiently high melting point to cause the mixture to maintain its form at the temperature of the body. No. 1 was used daily or every second day until the sinus or abscess was practically free from pus; then No. 2 was used, at first every second day, and later less frequently, until healing was completed. These mixtures were injected at 110° to 120° F., by means of an ordinary large glass syringe. Only just enough force was used to fill the cavity. The outer opening was closed with a gauze plug. The remarkable part of the treatment lay in the fact that cases in which the abscess cavity communicated with a bronchus would heal quite as rapidly and as perfectly as other cases, that symptoms of sepsis disappeared rapidly, and that in most cases in which there was no communication with the bronchi the discharge from the sinus soon became sterile.

Visceral Pleurectomy.—Dr. Alexander Hugh Ferguson of Chicago said that by this operation was meant the removal by operation of the thickened visceral pleura in cases of chronic empyema. In six cases in which he resorted to this operation the results had been all that could be desired. All the patients gained flesh and all cavities were completely closed. The youngest patient was twenty-three years of age; the oldest forty-five. The amount of visceral pleura removed varied from a strip an inch long to four inches wide.

Dr. Charles H. Peck of New York reported a case of stab wound of the heart in a colored girl. The wound was sutured successfully and the patient was well twenty-four days after the operation.

Dr. Willy Meyer of New York detailed a new method of esophagogastrostomy for intrathoracic resection of the esophagus.

The Prevention and Treatment of the Sequels of Perineal Prostatectomy.—Dr. James E. Moore of Minneapolis, Minn., said that perineal prostatectomy was a life-saving operation, but a grave one, and should not be undertaken lightly. It was accompanied by a mortality rate of a little over 6 per cent., and over 17 per cent. were either complete failures or were followed by some sequel that made the operation far from satisfactory. Owing to the age and bad condition of these patients there must be a high mortality rate. The nature of the operation was such that complications and sequels were bound to occur, but at the present time the mortality rate was too high and

the sequels too common. According to the latest statistics, 7.4 per cent. of these operations were failures, but in competent hands the patient should always experience sufficient relief to justify the operation, though he might not be completely cured. When a patient continued to suffer pain and tenesmus after the operation it was usually due to a pocketed bladder, diseased kidneys, or an incomplete operation. The prostate was an important sexual organ, and its removal by any route or method was sure to have a decided effect on the procreative powers of the patient. Owing to the reticence and untruthfulness of patients it was impossible to state how often this sequel followed, but it was certain that it occurred so frequently that every patient who was comparatively young in years should have this possible contingency stated to him before the operation was performed. Injury to the rectum was probably the most frequent complication, often causing death, and when a patient survived he was liable to have a urethrorectal fistula. Unskilful use of fingers, downward pulling by retractors, and too tight packing with gauze were the usual causes, by guarding against which this accident should be avoided. When the rectum was torn it should be immediately repaired. Frequently this would fail, but succeeded often enough to justify the effort. Stricture was a more common sequel than was generally believed, and was due to extensive removal of the prostatic urethra. We expected injuries to the urethra from other causes to result in stricture, and there was no reason why it should not follow this operation. Enough of the upper wall of the prostatic urethra should be preserved to secure an unbroken mucous surface extending from the bladder to the meatus. Extensive dissection of the perineum, especially when cross cuts were made, was conductive to stricture. Projecting portions of the urethra were sometimes left, which obstructed the flow of urine by acting as valves. Dribbling or incontinence was an occasional sequel of perineal prostatectomy, and was due to injuries to the neck of the bladder and to the compressor urethræ muscles. Instruments introduced into the bladder to draw the prostate down should be used with the utmost care, lest they injure the neck of the bladder. The compressor urethræ was the important sphincter, and should be preserved by entering the prostatic rather than the membranous urethra. The treatment of incontinence when once established seemed to be hopeless. Perineal fistula was a rare sequel, and was usually due to the deposit of lime salts, the removal of which relieved the condition. Epididymitis was an occasional sequel, but was usually of little consequence beyond the discomfort it caused, and was very often due to the injudicious passing of sounds.

(To be continued.)

Treatment of Sclerema Neonatorum.—Dionigi Tibone describes sclerema as a condition of the new-born, especially of premature infants, in which there is a hypothermia combined with slow and feeble pulse, and a solidification of the subcutaneous fat cells, with hardening of the skin. The infant becomes excitable by no stimulations, looks like a corpse, and is incapable of nursing. The indications for treatment are stimulation, artificial feeding, and keeping up the temperature of the infant. This last indication is carried out in various ways—by applications of external heat, by hot baths, by keeping the child in an incubator, and by enveloping its limbs in impermeable materials which keep the heat in, lessen the surface for radiation, cause fluidification of the subcutaneous fat cells, and make the slowed circulation more rapid. The author gives histories of 10 cases in which these measures were used with some success. The use of impermeable wrappers for the limbs is very simple and effective, as well as cheap, and does not interfere with the application of other means of calorification.—*Rivista di Clinica Pediatrica.*

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of August 14, 1909:

	Aug. 7		Aug. 14	
	Cases	Deaths	Cases	Deaths
Tuberculosis Pulmonalis	532	135	431	158
Diphtheria	207	15	173	20
Measles	256	16	216	16
Scarlet Fever	76	4	87	
Smallpox	..	....	..	....
Varicella	14	1	16	....
Typhoid Fever	72	14	71	9
Whooping Cough	45	6	44	13
Cerebrospinal Meningitis	5	6	4	5
Malarial Fever	....	....	....	....
Totals	1,207	197	1,042	227

Dryness of the Pharynx is often associated with atrophic rhinitis.

Dyspepsia in Malarial Subjects.—V. Raymond and L. Salignat have had under treatment at Vichy many cases of chronic malaria contracted in tropical countries, in which they have found chronic dyspepsias to exist. In thirty of these cases they have made accurate determinations of the stomach contents and gastric chemistry. They found that in 53 per cent. there was hyperchlorhydria, in 33 per cent. normal chemism, and in 13 per cent. hypochlorhydria. These troubles are found in recent as well as chronic cases of malarial poisoning, and are the results of various stages of the disease. The liver and spleen are also affected. There is hypertension and then hypotension of the portal circulation, and relaxation of the suspensory ligaments of liver and spleen. All sorts of symptoms are presented in gastric dyspepsia of malarial origin. In the beginning there is excitation of sensibility of the stomach, of secretion, and of motility. Later succeeds a period of depression, with diminution of secretion. In most cases there is more or less pronounced anemia. Treatment should include the use of quinine and hydrotherapeutic measures.—*Révue de Médecine.*

Tuberculous Endocarditis.—Francesco Fulci, after going over the literature with reference to the possible occurrence of tuberculous endocarditis, sums up by saying that the opinions of authors are still at variance as to the possibility of its occurrence. Perhaps these lesions are merely toxic, not caused by the actual presence of tubercle bacilli. This theory is supported by the absence of specific bacterial lesions and of specific histological formations. Lesions of the same kind can be produced in dogs by injection of emulsion of bacillus of Koch into the carotid artery, after ligature of a ureter made the day before the injection. The result is specific granulations disseminated over the internal surface of the left ventricle and auricle, the aorta, and ventricular surface of the aortic valves. This tuberculosis may be produced without any trauma of the heart, either by direct injection of the specific bacilli into the heart, or by carotid injection after suppression of the kidney function. The examination of the lesions showed necrotic, inflammatory, and reactive phenomena. The bacteriological examination showed few bacilli in the superficial fibrinous deposits when the germs were injected into the blood. The author sums up two groups of experiments on animals made by himself thus: he dissents from the opinions expressed by others in that he obtained no granules that were undoubtedly tuberculous; he never succeeded by endovenous injection in producing undoubted inflammatory alterations of the valves; Marchiafava after years of observation never encountered specific endocardial lesions in tuberculous subjects.—*Il Policlinico.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending August 6, 1909:

SEROLOGY OF SYPHILIS.*

BY RALPH C. MATSON, M.D.,

BACTERIOLOGIST STATE AND CITY BOARDS OF HEALTH; LECTURER ON BACTERIOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF OREGON AND NORTH PACIFIC DENTAL COLLEGE.

To those not familiar with the subject matter at hand, I propose to rehearse some of the most general principles upon which are based these kinds of researches, and that the procedures employed may be clearer to you I have introduced some simple drawings and patterns after the nomenclature of Ehrlich to illustrate the facts that lead up to and give substantial foundation to the Wassermann test.

Confining myself to the essential points, let us first briefly consider the different classes of antibodies. One class is relatively simple, and it is sufficient, in order to bring about a reaction, to put it in contact with the substance toward which, when in apposition, it is endowed with specific power of reaction. Fig. 1 represents diagrammatically the action of simple antibodies as may be seen in the principle of the Widal reaction. (*a*) The typhoid bacillus representing antigen A1 becomes agglutinated in the presence of typhoid serum representing antibody A2; (*b*) the principle of antitoxin in diphtheria is based on the principle that diphtheria toxin B1 (antigen) and antitoxin B2 (antibody) are mutually neutralized. These simple antibodies are made up of two parts, the zymophore group (in black) to which they owe their action on the antigens (on the left) when united with them by means of haptophore-antigenophile groups (in white). These antibodies are specific to their particular antigen and unite only when they are reciprocal. Given a known antigen, one could recognize an unknown antibody by mixing them together; if they combined they must be identical.

The other class of antibodies act in a manner more complex. These are the "amboceptors" of Ehrlich or "substances sensibilatrices" of Bordet. Like the simple antibodies, they are specific in combining, but unlike them they are incapable of action in themselves, requiring the presence of a third substance the "alexine" of Bordet or "complement" of Ehrlich. The "amboceptors" must be separated into two classes, natural and artificially prepared ones. Natural being found in an inequal manner among the animal species. One species will contain one kind, another, closely related, contains amboceptors partly different. The artificial amboceptors are created by injecting an animal with the body or antigen to which the amboceptor corresponds. The introduced body has the power to stimulate the animal body cells to produce its specific antibody. Hence the term "antigen" coined by Wassermann meaning generator of antibody.

Every amboceptor has an antigen, and only one, to which it fits and upon which it acts, and by such action the antigen becomes sensitive to the action of the complement. The complement, unlike the antigen and amboceptor, is not specific; it is found in all blood and acts upon any antigen providing it first be sensitized or acted upon by amboceptor. Fig. 2 diagrammatically represents the relationship between antigen (on the left), amboceptor (in the center), and complement (on the right). The chemical diversity of the antigens is indicated by the diversity of shading, the diversity of their amboceptorophile group is indicated by the diversity of their forms. The diversity of the amboceptor's antigenophile group is indicated by diversity of shape. The possibility of reciprocal adaptation is marked by placing them oposite to their respective antigens. The complementophile group is shaped the same in all, showing the complement is capable of adapting itself to all amboceptors. (*a*) Shows the antigen of syphilis is reciprocal with amboceptor of specific luetic serum; (*b*) shows the antigen in form of sheep corpuscles is reciprocal with amboceptors of immune rabbit serum (rabbit inoculated with sheep corpuscles). The complement is shown on the right capable of fitting any amboceptor.

Bearing in mind that the antigen and amboceptor are specific and can unite only when alike, if we add antigen in the form of sheep's red blood cells and amboceptors in the form of rabbit's blood serum that has received inoculations of lamb's corpuscles, known hereafter as specific rabbit serum or specific hemolytic serum, a union will take place (Fig. 3), evidenced in a very pretty reaction termed hemolysis, which consists in a dissolution of the lamb's corpuscles with a liberation of their hemoglobin easily seen macroscopically by the transparent solution of hemoglobin as contrasted with the previously turbid non-hemolyzed blood which would obtain if normal rabbit's blood serum were added (Fig. 4), because amboceptors are absent, and the complement has no power in its absence. However, if the specific rabbit's serum is heated to 56° C. one-half hour it loses the power to dissolve lamb's cells (Fig. 5). This is termed "inactivating the serum," because the complement has been destroyed, but if to this mixture normal serum of any source is added, as guinea pig serum, the rabbit's serum again acquires the power to dissolve lamb's cells (Fig. 6); for the normal serum supplies that which the heat has destroyed (the complement), it "reactivates it." Thus it will be seen that hemolysis depends upon two substances, the amboceptor which is present only in blood of the injected animal and is thermostabile, *i.e.* (withstand 56° C. one-half hour). The other, the complement, is present not only in the blood of the injected animal, but also in the blood of

*Read before the City and County Medical Society, Portland, Ore., March 4, 1909.

any animal and is thermolabile. (56° C. one-half hour destroys it.)

The union of the complement, amboceptor or immune body, and cell is known as the hemolytic chain, and is necessary for hemolysis to take place. The union here is, amboceptor binds with the cell and then the complement binds the amboceptor, when all three substances make one; there is consequently in this case fixation and absorption of the complement, or deviation as it is termed.

We furthermore understand that not only will cellular elements when injected create amboceptors which are specific, but bacteria or bacterial elements, when injected into an animal or existing there pathologically, likewise give rise to corresponding amboceptors or immune bodies which are specific and have the power to fix themselves to bacteria if mixed with them, by one combining group, and to the complement by the other combining group. This is the principle of which Bordet and Gengou took advantage to determine the nature of an infection. By mixing the inactivated serum for diagnosis with the supposed bacteria and adding the complement in the form of normal guinea pig serum, if the serum in question contained antibodies against the bacteria a binding between bacteria, antibody, and complement took place. This is proved by the fact that if lamb's corpuscles are now added, and also a heated specific hemolytic serum, no solution of the corpuscles or hemolysis takes place, because the hemolytic amboceptor has no appreciable effect upon the lamb's corpuscles in the absence of complement or alexin, which is already bound up with the bacterial amboceptor (Fig. 7). Hemolysis would occur, however, if the serum in question did not contain reciprocal antibodies for the antigen, for under such circumstances the complement would have no affinity for the bacterial antibody and would remain disengaged to act upon the lamb's corpuscles through the specific hemolytic amboceptor (Fig. 8).

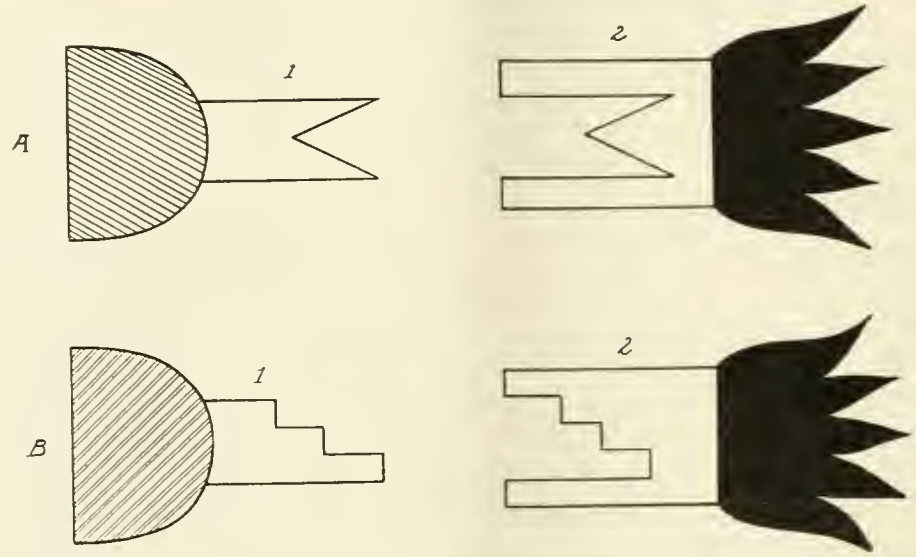

FIG. 1.—Scheme of simple antibodies. (Diagrams modified from *La Presse Medicale*, after Hallion).

The proposition then is this: If we add a known bacterial substance to an unknown serum, which has been freed from complement by heating to 56° C., and find that this mixture has the power to absorb complement we have evidence that the unknown serum contains antibodies which are capable of com-

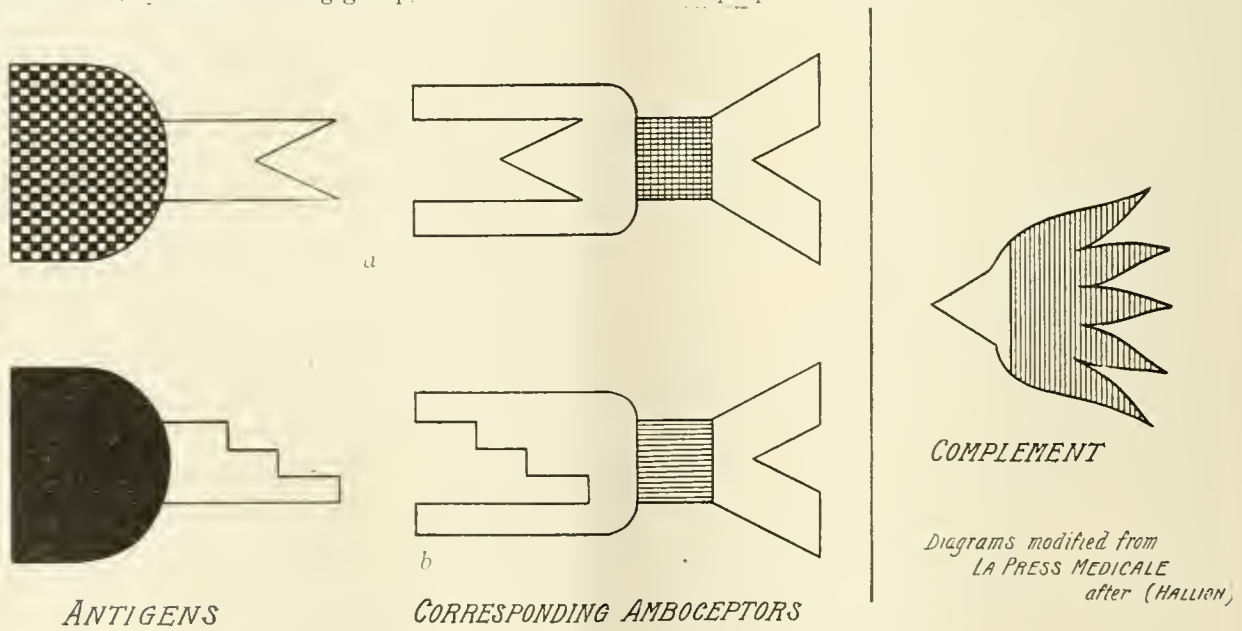

FIG. 2.—Scheme of antigens, amboceptors, and complement.

bining with the known bacteria or an extract of them. Therefore, these antibodies must be a result of an activity of that genus of bacteria. Thus is established the identity of an unknown serum by using known antigen, or vice versa the identity of an unknown organism by using a known serum. Furthermore, the proof that antigen, antibodies, and complement have united may be established by adding lamb's corpuscles and specific hemolytic serum. The lamb's cells, it will be seen, remain unaltered because the complement is already engaged. By means of this ingenious and complicated method, Wassermann, Neisser, and Bruck,[1] using an extract of infected syphilitic organs as antigen, have succeeded in establishing the presence of syphilitic antibodies, first in the serum of monkeys inoculated with syphilitic products, then in individuals afflicted with syphilis, and lastly Wassermann and Plaut in the cerebrospinal fluid of tabetics and general paralytics.[2] Although it is the unanimous opinion of those who have studied the reaction that it is of indisputable practical value, nevertheless the theoretical principles on which it is based still remain undecided.

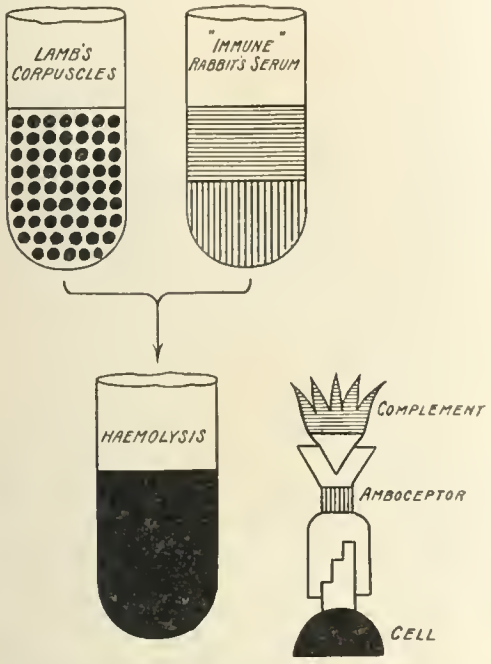

FIG. 3.

Kraus and Volk and Marie and Levaditi were the first to bring out facts contradicting the specificity of the test, when they showed that not only did syphilitic liver extract in the presence of specific sera absorb complement, but that normal liver likewise had that power. This fact was soon confirmed by Plaut, Fleishmann,[3] L. Michaelis,[4] Landsteiner, Braun, and Weil,[5] the latter stating the test was not specific, for he had obtained a positive reaction with syphilitic sera, using extracts of sarcomas instead of luetic liver as antigen. However, later[6] he failed to get a positive reaction in control cases, and obtained 88 per cent. positive reactions in syphilis. Therefore, since the normal liver extracts gave a positive reaction only in the presence of syphilitic serum, the practical value of the reaction is not diminished.

Later Landsteiner, Porges and Meyer, Levaditi and Yamanuchi[7] made the important observation that, contrary to true antigens, the active substances in both syphilitic and even normal livers are soluble in alcohol and sometimes in ether. Following up these observations, experimenters have worked with substances of known chemical combination to replace the liver extract. Landsteiner demonstrated that lipoid substances, especially lecithin[8] would give the reaction. Sachs, Altmann, and Levaditi obtained the reaction with taurocholate, glycocholate, and oleate of soda. Benecke thought this explained why fetal livers were superior since they contain many fat vacuoles enveloped within a soap membrane. Fleishmann[9] obtained positive results using cholesterin and vaseline.

Success having in a way been obtained in finding a chemical substitute for the liver extract, which, owing to the necessity of an untreated liver, was difficult to obtain, it was thought the serum diagnosis could be very much simplified by the use of some such substance. For this purpose Porges[10] and Meyer used lecithin, Sachs and Altmann olein and alcohol as antigen, finally Klauser[11] was satisfied to use distilled water, to which he added the suspected serum, claiming the appearance of a precipitate in a few hours was evidence of syphilis. However, the matter is not so simple. Recent researches of Kraus, von Eisler, and Stumme have shown Porges reaction also positive in tuberculous and malignant cases.[12] Klausner's[13] reaction upon further study is found to have no diagnostic value since it is equally positive in other diseases.

Wassermann insists that extracts be made with salt solution to make the test reliable. The bile salts and oleate of soda, however, seem to give good results. Mayer and Proescher[14] find a 1 per cent. solution of sodium oleate in 0.85 per cent. sodium chloride very satisfactory as antigen.

Even the application of the method devised by Wassermann and his associates is not entirely free from all criticism, for it has been met with in some other morbid states. Thus it has been found positive in experimental trypanosomiasis[24] as well as in

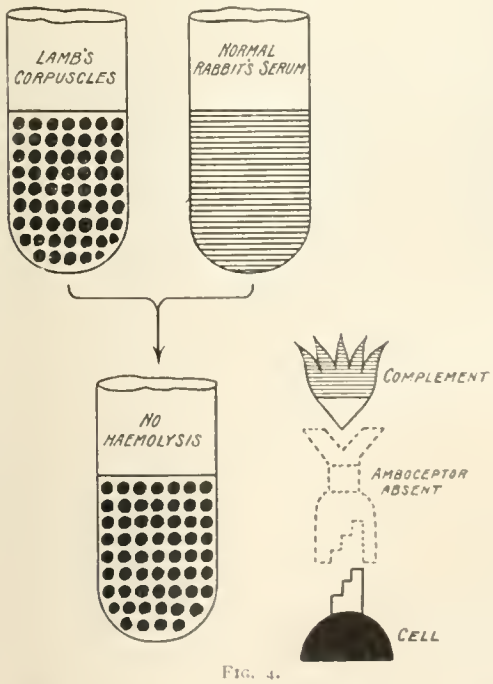

FIG. 4.

frambesia (yaws), but here we deal with diseases which, through their etiological factors, offer much analogy with syphilis and like frambesia have even a great clinical resemblance to it.

As in every other important laboratory method of

diagnosis we might expect criticism concerning the actual value of the method. On the other hand, the thousands of cases in which it has been applied has affirmed its specificity to a large body of eminent workers, and we might well ask if, in those few

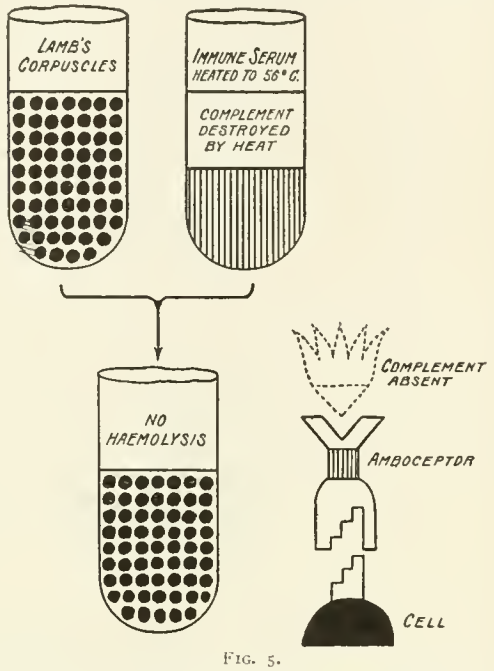

Fig. 5.

cases where syphilis could not be ascertained, there might be a syphilitic infection, hereditary or acquired, leaving no trace clinically or anatomically. The results of those who have examined a large number of sera are very uniform, *i.e.* that about 80 per cent. of syphilitic individuals, irrespective of type, give a positive reaction, and that the blood of the patients who positively have no syphilis invariably gives a negative reaction.

The following are some of the results obtained by various workers: Wile[15] investigated 100 cases, testing both the urine and blood serum, he obtained a positive reaction in both the urine and serum in 66 2-3 per cent. of the syphilitics, but concluded the urine reaction to be not of so much value as the blood serum. Kroner[16] obtained 75 per cent. positive reactions in 40 cases of suspected syphilis; all controls were negative. Meier[17] obtained 81.7 per cent. positive reactions in 118 syphilitics; all controls were negative. Citron[18] examined 108 cases of clinical or suspected syphilis; 74 per cent. reacted positive. Müller[19] examined 197 cases of syphilis; 94 per cent. were positive. Of 500 controls, 97 per cent. were negative. Butler[20] examined 105 cases and 20 controls in which syphilis could be reasonably excluded by examination and history. All controls reacted negative, including cases of typhoid, pneumonia, neurasthenia, etc. Butler grouped the cases under two heads: (1) Cases with manifest or suspected syphilis and cases giving a history; (2) cases with lesions of the nervous or cardiovascular systems in which syphilis was either acknowledged, denied, suspected, or unsuspected. Of the first division there were 61 cases. In the primary stage 100 per cent. were positive. In the second stage 96 per cent. were positive. In the third stage 95 per cent. were positive. In the latent cases 52.8 per cent were positive. Of the second division there were 44 cases, of which 75 per cent. were positive. Fleishmann and Butler[21] examined 41 syphilitics and suspects; in 70.7 per cent. cases reactions were positive. Fischer and Meier[22] examined 114 luetics, of whom 83.7 gave positive reactions.

Since different authors have used different methods of classification, we may expect a difference of opinion as to the value of the test. For instance, Citron reports 307 cases; 156 were nonsyphilitic, and all gave a negative reaction; 108 were of different types, and 74 per cent. were positive. 43 were cases of paresis and tabes and 79 per cent. were positive. Here no distinction between types is made. While in another report Blaschko obtained the following results, according to the stage of the disease: 90 per cent. positive, in initial stage; 98 per cent. positive, in first stage; 91 per cent. positive, in late syphilis, no symptoms; 57 per cent. positive, in late syphilis; 60 per cent. positive, with cerebrospinal symptoms. It will be observed that the percentage of positives will be higher in early untreated cases than in late treated cases, and authors should have some uniform system of reporting results.

As in many laboratory findings improper interpretation of results by clinicians is responsible for much undue criticism, but this does not lessen the value of the test in reliable hands. It must be remembered that effectual treatment may cause the reaction to disappear or be absent. A positive reaction means that the patient has syphilis, hereditary or acquired, but does not necessarily mean that the present pathological process is due to syphilis; he may be suffering from a coincident infection and clinical facts must decide this point. A negative result means that your patient either has not syphilis, or has latent syphilis; it does not necessarily mean the patient is cured.

As in many valuable laboratory aids in diagnosis the technique is laborious. One must be prepared for many disappointments, difficulties will be encountered which are most discouraging. Butler,

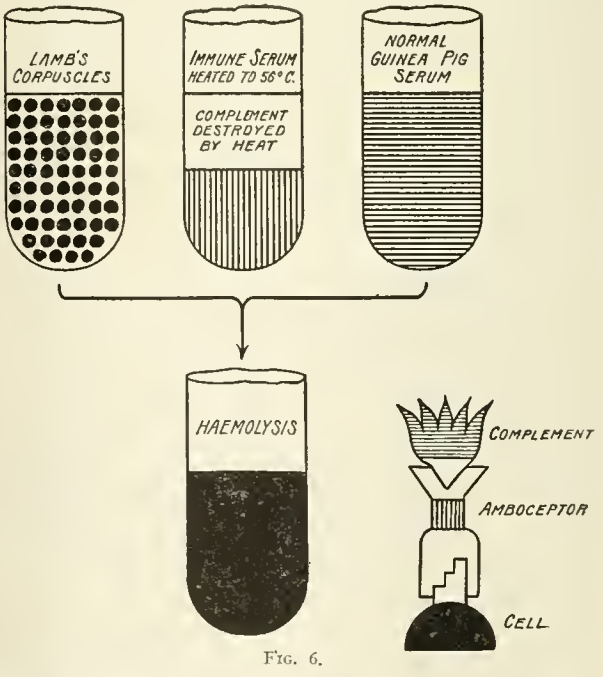

Fig. 6.

Marchildon, and others have shown that an alcoholic extract of liver is just as accurate as the salt solution, and keeps well at room temperature; this simplifies the technique considerably.

To carry out the test the following reagents are

employed: (1) Serum for diagnosis. Easily obtained by filling a 2 c.c. Wright capsule securing the blood from the thumb after the application of a rubber band. This is allowed to coagulate and the serum drawn off, after separation, into a pipette.

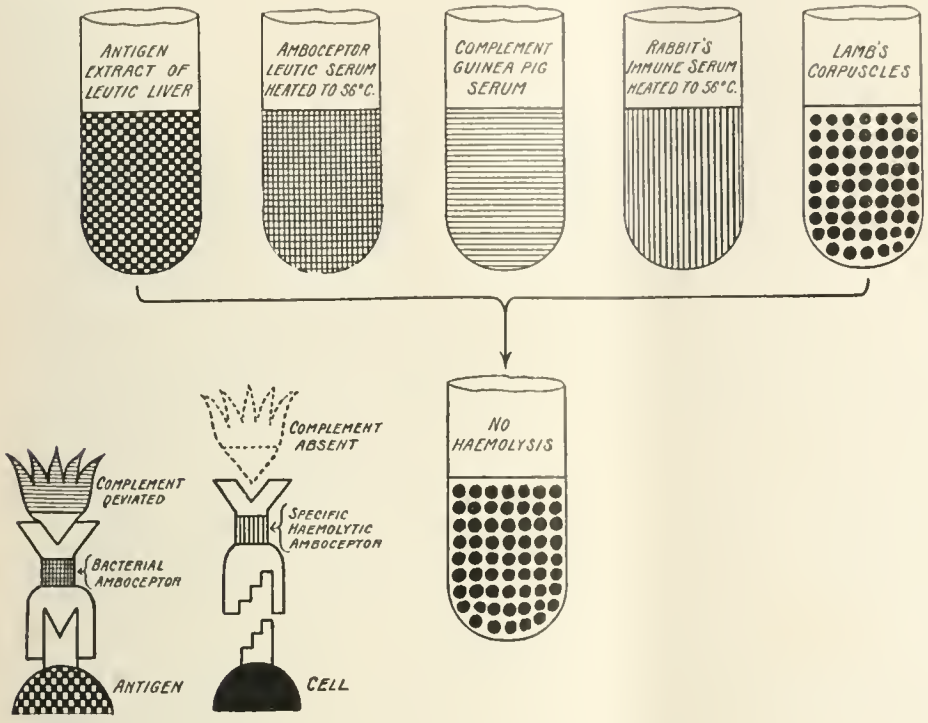

FIG. 7.

Care must be taken to avoid drawing up red blood corpuscles; should this happen, centrifuge the specimen to clearness. Seal the tip of the pipette after drawing off the serum, and after creating a positive pressure in the rubber teat, drop in water bath and inactivate by maintaining at 56° C. for one-half hour. (2) Control sera. Two or three are collected and treated in the same manner. (3) Antigen or organ extract. Made by taking a fetal luetic liver or guinea pig heart, 1 gm. to 50 c.c. of 95 per cent. alcohol, after rubbing up with sand in a mortar; this is placed in a flask and kept at 60° C. one hour in water bath; it is then filtered and kept at room temperature in a dark place ready for use. (4) Complement. A guinea pig is killed and blood from the heart is collected in a sterile tube and placed on ice to coagulate. After the serum has separated it is drawn off and kept ready for use. It is well to collect and prepare the pig serum the day before. The complement is most active twenty-four hours after collecting the serum. This can be kept ten days if 1 per cent. sodium chloride is added and frozen after placing in small tubes. These can be thawed out when required. (5) Hemolytic serum. Made by injecting a rabbit every week or ten days with 5 c.c. of a 5 per cent solution of washed sheep's blood corpuscles suspended in 0.85 per cent. salt solution. Four or five injections are given and the blood collected from the heart a week or ten days after the last injection. It is placed on ice. After the serum separates, pipette into test tubes, seal off, and inactivate at 56° C. one-half hour. This must be kept on ice ready for use. If one prefers, a rabbit can be inoculated with calf's blood; 50 to 80 c.c. may be injected intraperitoneally on three occasions, one week apart. Care must be taken that all serum is thoroughly washed, otherwise anti-complements are generated in the rabbit's serum. (6) Washed sheep's blood corpuscles. Sheep's blood is obtained at the time of killing, collected in a sterile flask containing beads and shaken vigorously. A small quantity is washed in 0.85 per cent. salt solution two or three times and then suspended in salt solution to the extent of 50 per cent.

The next step is to test the material. This includes: (1) Standardizing the amboceptor. This is accomplished by making dilutions of the amboceptor with 0.85 per cent. salt solution and determining what dilution in one drop dose dissolves one drop of a 50 per cent. suspension of sheep's corpuscles plus

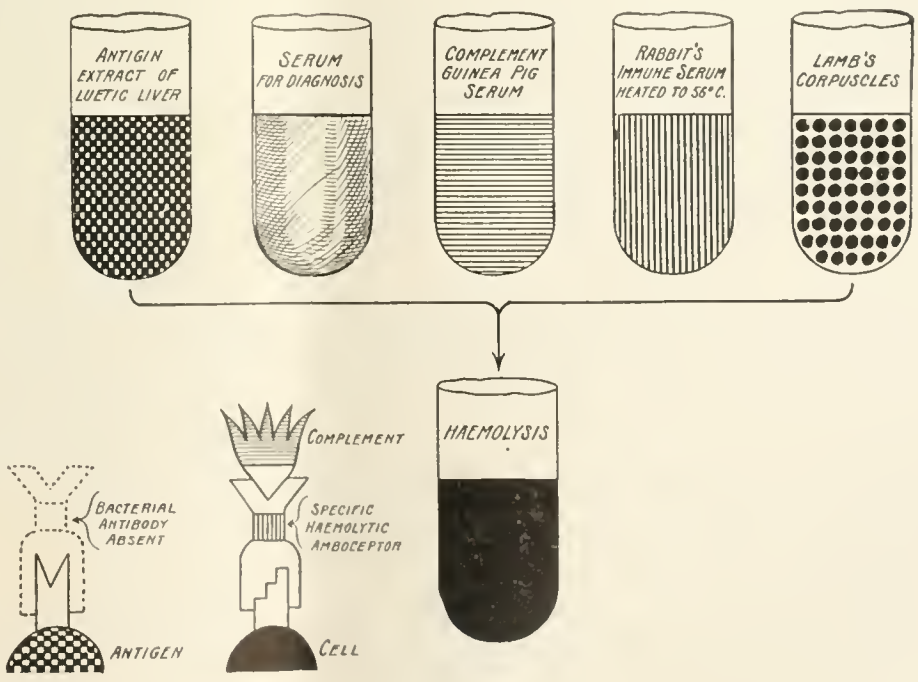

FIG. 8.

one drop of complement in one hour at 38° C. Then twice this strength is used in the test. (2) The extract must be tested to see that it alone is not capable of hemolyzing sheep's corpuscles, or binding up complement. This must be done before each test, and is accomplished by using one drop of extract and one of complement in ten drops of salt solution, incubating one-half hour at 38° C., and then adding amboceptor and blood corpuscles; after reincubating hemolysis should occur in one-half hour. The binding of the complement by the antigen has been a source of great annoyance in the last series of tests we have put up. (3) The sheep's corpuscles must not already be hemolyzed. This can be determined by simply looking at the corpuscle suspension and avoided by using fresh mixtures. (4) The complement must be known to be active. You may be sure of this if the guinea pig serum is fresh.

Tubes should be freshly made of glass tubing, avoiding that which is alkaline; each specimen requires two tubes; these may be two inches long and about one-fourth inch in diameter. A fresh pipette should be made for each, the antigen, amboceptor, complement, and corpuscles. The sera for examination are already contained in pipettes and can be dropped by simply breaking off the tip. The reaction is then carried out as follows: The tubes are arranged in racks and numbered. Add a drop of antigen* to one of the two tubes used for each specimen, then add a drop of serum to each, and finally add a drop of complement to each tube. Shake the tubes and place in the incubator for one hour at 38° C. Remove, add a drop of amboceptor and a drop of a 50 per cent. suspension of sheep's corpuscles, shake, and reincubate for one and one-half hours. The result can then be read. For the examination of one suspected blood, including necessary controls, the test may be set up as follows:

	Incubate 1 Hour.			Incubate 1½ Hours.			Result Should Be
Tube	Liver Ext.	Serum of	Pig Serum	Rabbit Serum	Sheep's Corps.		
1	1 drop	Normal	1 drop	1 drop	1 drop,	50% sol	Solution.
2	"	"	"	"	"	"	No solution.
3	1 drop	Luetic.	1 drop	"	"	"	"
4	"	"	"	"	"	"	Solution.
5	1 drop	Suspect	"	"	"	"	If luetic, no solution.
6	"	"	"	"	"	"	Solution.
7	1 drop		"	"	"	"	"
8	"		"	"	"	"	"

All controls with sera alone, with normal sera, and with antigen alone should be hemolyzed. If hemolysis has occurred in the tubes containing suspected sera plus antigen the reaction is negative, if hemolysis has not occurred the reaction is positive. I cannot urge too strongly the necessity of attention to the details of the technique, the testing of the material, and of having a goodly number of controls scattered among the suspected and known sera. Only in this way can disappointing and unreliable results be avoided.

I wish to report the examination of seventy-five cases, fourteen of which were control bloods from which syphilis could be excluded and all were negative. The remaining sixty-one I have arranged after the grouping of Butler under two main heads. First, cases with manifest or suspected syphilis and cases giving a history of syphilis. Second, cases with lesions of the nervous or cardiovascular systems in which syphilis was either acknowledged, denied, suspected, or unsuspected.

*Personal communication from Butler states this is as reliable as the former method of using dilutions.

The first class represented thirty-seven cases. Of these there were twelve in the primary stage either with initial lesions or before the appearance of secondary symptoms; all were positive. In the secondary stage there were nineteen cases; eighteen were positive and one negative. In the second division there were twenty-four cases: nineteen were positive and five negative. Taking the entire thirty-seven cases of the first group, which comprised what we might term known syphilitics, 92 per cent. gave a positive reaction, and, upon analysis, in the first stage 100 per cent. were positive. In the second stage 94.8 per cent. were positive. In the third stage 66 2-3 per cent. were positive. My low percentage in the third group is due to the fact that I have grouped the third stage and the latent cases together. It will thus be seen that the test is of greatest value in early syphilis. Whether the diminishing value of the test is influenced by treatment I am not prepared to say. However, of the six cases in the third stage, the disease had existed from six to nineteen years in the positive cases and had been treated in an irregular way, while the negative cases were of fifteen years' duration each and well treated. These facts would lead one to think that treatment influences the reaction. Citron[23] observed that under vigorous treatment the reaction tends to disappear. Butler, Fleishmann[24] and Wile[25] have stated that patients under treatment frequently react negatively.

It is impossible to give case histories and clinical data in this brief paper, but some comment on the cases comprising the second division would seem advisable. This group consisted of what might be termed suspected syphilis. There were nineteen positive and five negative cases. Of interest are the following. Case 1.—Patient of Dr. Buck had multiple adenitis, did not remember an initial lesion (wife had had syphilis), reacted negative to tuberculin, gave a positive syphilitic reaction, and has improved under luetic treatment. Case 2.—Patient of Dr. Baar, pernicious anemia, had had syphilis years before, but thought he had been well treated, reacted positive. Case 3.—Patient of Dr. A. E. Mackay, enlarged liver, diagnosed as parasyphilitic, no history of syphilis, but led a life of dissipation, reacted positive many times. Case 4.—Patient of Dr. Coffey, cancer of the rectum, diagnosis confirmed by microscopic findings, formerly diagnosed as syphilis, reacted negative. Case 5.—Patient of Dr. Bell, diagnosed carcinoma of liver. No history of syphilis, intense jaundice, reacted positive.

A positive reaction has been obtained in cancer by others. Marchildon[26] examined the sera of thirteen carcinoma cases and obtained one positive reaction. The case was a woman who presented no signs of syphilis but who had been a prostitute. Weil and Braun,[27] Elias, Neubauer, Porges, and Salmon[28] have called attention to a slight reaction in cancer. But in all the cases so far reported the disease was far advanced and offered no difficulty of diagnosis, and, considering the rarity of the reaction in these cases, it does not lessen the clinical value of the test. Another case of this group was that of a physician who thought he had contracted syphilis through vaccination, and has not only attributed every complaint to this supposed accident, but has antagonized the principles of vaccination very severely. A recent sore throat reminded him of his

old malady. He presented no signs of the disease, and reacted negative twice. This was clearly a case of syphilophobia. Trivial ailments are now ignored and he believes in vaccination. The value of this test in syphilophobia is apparent.

The Wassermann reaction has a large field of usefulness in every department of medicine. Bab[29] calls attention to the vital importance of applying the test to the milk of a woman deciding to nurse a syphilitic infant. He examined the milk of four syphilitic women and found antibodies in large amount. Syphilitic children would be materially benefited by imbibing such milk rich in immune substances. If only the child is syphilitic, an examination of the milk will show whether the mother is a latent syphilitic. If no antibodies are found she should not nurse the child lest she become infected. Opitz[30] believes it of greatest importance to the obstetrician. In one hundred and four maternity cases he obtained a positive reaction in ten cases, the findings being proven as correct by the conduct of the cases later with the exception of two. He would accept no wet nurse without first applying the test. To the neurologist the test is valuable; it has made it possible to obtain evidence of syphilis in many cases of tabes, pachymeningitis, general paralysis, and other parasyphilitic infections. Wassermann and Plaut[31] examined the cerebrospinal fluid of forty-one paralytics, 78 per cent. of which was positive. In nineteen controls all were negative. Marie and Levaditi,[32] in an examination of the cerebrospinal fluid of seventeen patients without general paralysis, proved the test negative, while it was positive in 73 per cent. of patients in various phases of the disease, wherein they demonstrated specific antibodies in the blood and cerebrospinal fluid.

CONCLUSIONS.

The rarity of a positive reaction in normal serum and the high percentage of positive reactions in syphilis or suspected cases clearly shows the test to be of much value. A positive reaction is found with greatest frequency in early cases, and least frequently in latent cases. A positive reaction means that active syphilis exists, but does not necessarily mean that the present pathological condition is due to syphilis; that must be determined clinically. But it does indicate that there should be an exhibition of antisyphilitic treatment. A negative result may be interpreted in many different ways. A negative reaction occurring in one who has had syphilis does not mean absolutely that the patient is well, but that the infection, if present at all, is quiescent. If a negative reaction occurs in an early suspected case it is from 95 to 100 per cent. against syphilis. If obtained in a suspected secondary case the chances are from 90 to 100 per cent. against syphilis. If obtained in a suspected tertiary case the chances are 75 to 95 per cent. against syphilis. If obtained in suspected latent cases the chances are from 50 to 75 per cent. against syphilis. If obtained in a suspected parasyphilitic the chances are 70 to 80 per cent. against its existence. Since antisyphilitic treatment may cause the reaction to disappear it may be an index as to the efficiency of a line of treatment in that particular case. As a diagnostic method it is of probably greater value in syphilis than the agglutinin reaction in typhoid, and as Fornet[33] suggests on account of the importance of serum diagnosis from a practical standpoint, it is to be hoped that modern municipal laboratories will be equipped to undertake these examinations and place the results gratuitously at the disposition of practitioners.

In conclusion I wish to extend my hearty thanks to Dr. W. J. Butler who has given me many valuable suggestions and has placed antigen at my disposal; to Dr. A. E. Mackay, for much valuable material in the way of known cases for controls, and to Mr. Frank McCauley, for conducting the immunization of rabbits, and for constant help in carrying out the many details of the test.

A SEVERE CASE OF SCARLATINA AND OF DIPHTHERIA SUCCESSFULLY TREATED WITHOUT MEDICINE.*

By WM. HANNA THOMSON, M.D., LL.D.

NEW YORK.

On January 26, 1909, I was called by Dr. Geo. B. Ferguson, of the Bronx Borough of New York City, to see in consultation with him a girl, aged five years, who began with a sudden sharp onset of scarlatina in the night, five days before. The throat was very early affected and the characteristic rash ran its usual course, with a high temperature of 104.2° by mouth.

On the third day of the scarlatina a diphtheritic exudation appeared, which rapidly spread. Dr. Ferguson administered 10,000 units of antitoxin,

*Read before the American Association of Physicians, Washington, D. C., May 12, 1909.

and on the next day 5,000 more, but no effect on the exudation followed, and the membrane increased so that when I was called in on the sixth day of the scarlatina and the third day of the diphtheria, the membrane covered the uvula, both palatal arches, the tonsils and the pharynx, so that all these parts were practically hidden by the overlying membrane. The child was wholly unable to swallow, the glands on both sides of the neck were swollen, and the breath had a gangrenous odor. What concerned me most, however, was the unfavorable aspect of the countenance. The child was apathetic and presented a picture of serious septic infection. The pulse was weak and thready.

When we retired for consultation, I told the doctor that it was useless to think of administering any medicine, first, because the child was wholly unable to swallow, and secondly, because we had no medicinal remedies for any of the exanthemata, while it was plain that the diphtheria antitoxin would no longer avail in this case. Meanwhile the hypodermics of strychnine given for her cardiac and general prostration would be no more effective than emptying the little syringe into the grate fire. The only recourse, therefore, was to deal with her throat as we would wash a dirty sidewalk with a hose. I recommended, therefore, that two gallons of hot water, with two teaspoons of chlorate of potash and five drops of oil of peppermint dissolved in it, be made, to pour into her throat every two hours day and night, from a fountain syringe bag elevated six feet above her head. To prevent her gagging or swallowing any of the water, her mouth was to be kept wide open by a rubber ball held between the teeth.

For the first few days the patient felt such relief from this douching that she offered no resistance. Great quantities of the exudates came away with the return current. On my second visit two days afterwards, though the patient was still unable to swallow, I was gratified to note a marked change in her expression, and the enlarged cervical glands looked smaller. On my third visit two days after that, she could swallow, though extensive diphtheritic patches still remained. I then told the doctor that now we were as if in a canoe shooting a rapid with these rocks ahead. First, abscesses in the ears from the scarlatina; secondly, pneumonia, which in my experience carries off twenty per cent. of the fatal cases of scarlatina; thirdly, pleurisy, with a special tendency to empyema; fourthly, cardiac paralysis from the toxin of diphtheria; and lastly, scarlatinal nephritis. All of these occurred in their order except the last, the kidneys never showing the least disturbance. The very next morning after my third visit, Dr. Samuel Goldstein, the aurist, found abscesses in both ears, which, on puncturing the drum, discharged profusely, and continued to do so for over a week, but by his assiduous and skillful management the ears recovered perfectly. On the eighth day of her illness, the temperature, which had fallen to 102°, rose to 105°, and with it there was a marked rise in the leucocyte count. I then found a patch of pneumonic consolidation in the left midscapular region, which was farther surrounded by an area of pleuritic rales extending to the base of the lung posteriorly. Nothing was prescribed for this complication except to continue the throat douching. In five to seven days both the pneumonic signs and the friction rales disappeared; the throat was clear of all diphtheritic patches, the cervical glands had become normal, and the patient was very hungry. But the pulse now became very weak and intermittent, and then for the first time, on the 25th day of her illness, she took medicines in the form of cardiac stimulants in a pill of powdered squills, caffeine, and strychnine. I may add that I was careful not to administer digitalis, because I have seen very painful results from giving digitalis in diphtheritic weakening of the heart, not only because digitalis then fails to increase the power of the heart's systole, but because the arteries at such times seem to become especially sensitive to the arterial contraction, which is one of the effects of this drug. However, the recovery of the heart was very slow, and it continued to be weak and intermittent for six weeks. The child is now quite herself again, except for weakness of the legs, and a muffled, nasal voice from paralysis of the palate.

The history of this case seems to me to support the view that the characteristic complications of scarlatina arise not so much from the original infection as from the invasion of virulent streptococci through the portal opened for them by the local angina in the throat. From them it is that the successive series of tissue changes and inflammations develop. In other words the exanthem first inflames the throat, and the streptococci then do the rest. In this sense scarlatina becomes as local a source of toxemia as diphtheria itself is. With diphtheria also, when ulcerated surfaces are present, mixed infections occur which may wholly neutralize the action of its specific antitoxin.

All this illustrates an important principle which the profession has only recently learned to recognize, and which is that the specific and often fatal complications which follow a particular infection are most commonly due, not to the primary infecting agent directly, but rather to the supervention of invasion by quite different microorganisms. Thus in a bad case of smallpox, we have to contend in succession with two different diseases: The first is variola, whose initial stage of three days has its own severe and characteristic constitutional symptoms ending in its specific vesicular eruption. This runs its course in five days, after which everything seems to subside: pulse and temperature fall, the head and spinal pains, with the gastric disturbance, disappear, the tongue cleans, and both appetite and sleep return. But now a condition supervenes which a surgeon who carefully disinfects the skin before he makes the smallest incision in it, might well regard with dismay. All of the vesicles with their hitherto clear liquid contents now become infected by organisms always present on the skin and turn into swollen pustules containing myriads of staphylococci and streptococci. This latter infection gives rise to the symptoms of acute pyemia induced by the widespread cutaneous ulceration. If only we could sterilize the skin as the surgeon does, so soon as the variola papules appear, we would rob smallpox of most of its terrors, except in those rare cases when variola itself kills before its own eruption appears.

Effective local treatment, therefore, is as much indicated in scarlatina as in diphtheria, in that early stage when they are still virtually local affections, and for this purpose nothing is so certain to fulfil the requirements as a strong stream of water. This can occasion no local injury, and meanwhile it removes great quantities, not only of poisonous exudates, but actively stimulates healthy throat secre-

tions along with a free flow of posterior nasal fluids. When properly applied, no gagging occurs, as so often accompanies throat swabbing, and which itself may not unoften set up inhalation pneumonia. The scarlatina otitis also becomes a much milder complication than that which leaves the patient hard of hearing for a life time and which is said to be the cause of twenty per cent. of deaf mutes in our asylums. I would recommend throat douching, therefore, at the earliest onset of scarlatina, with the first signs of sore throat, before the various kinds of streptococci can gain entrance. This measure is equally indicated in diphtheria, first for lessening the absorption of its toxin, and then for preventing the invasion of streptococci through the ulcerated mucous membrane. When general infection has already occurred, as in this case, the prevention of further invasion may enable the patient's resistant powers ultimately to cope with and overcome the enemies which have made their way into the blood and tissues. I am also fairly certain, from my experience, that the relatively late occurrence of scarlatinal nephritis is preventable by throat douching on the same principles.

23 East Forty-seventh Street.

A LARGE GLIOMA GROWING FROM THE BASAL GANGLIA PRODUCING SYMPTOMS SUGGESTIVE OF A GROWTH IN THE FRONTAL REGION.

By THEODORE DILLER, M.D.,

PITTSBURG, PA.

CLINICAL PROFESSOR OF NEUROLOGY, UNIVERSITY OF PITTSBURG.

The case is that of a mill worker, a married man, 41 years of age. There is no history of specific disease. His previous history is negative.

I examined the patient for the first time April 27, 1904. He was at that time under the care of Dr. I. J. Moyer, at the Mercy Hospital. The first symptoms of his trouble were noted in January, 1902—about two and one-quarters years previous to the examination. These symptoms consisted of what the patient called "smell attacks." These attacks occurred at comparatively short intervals while he was at work in the mill and consisted of a state of mental confusion during which he smelt an odor; and sometimes the odor preceded the confused period. He was compelled to sit down during these "smell attacks" and rest for some minutes. He never fell during any of them, nor was he ever unconscious.

By the summer of 1902 he was free from these attacks and seemed entirely well. But a little later he began to suffer from pain located in the back of the head. Headache was to him a new thing, as he had never in his life suffered from it before. It became very severe in character. His wife stated "he thought he would go out of his mind." About this time his eyesight began to fail and has continued to do so ever since. The headache, with occasional interruptions, has grown more and more severe up to the present time. It was especially severe during the last three months of 1903. For the past three months the headache has been located in the frontal as well as the occipital region. Occasionally it is located in the frontal region alone, but more commonly in both frontal and occipital regions. Some of the headache is also referred to the vertex. The pain is rather more severe on the right than on the left side.

For the first time in his life he suffered a "convulsion" in July, 1903. Again on February 1st of this year the patient had another "convulsion"; and between that day and the present time (April 27) he has had about a dozen similar attacks. In these attacks he became unconscious, stiff, cold, pale, and breathed heavily. There was apparently very little movement. The patient seemed to sink away; and it is perhaps doubtful whether the attack should be called convulsive movements. For a month past the patient has had some twitching in the right face and mouth. This lasts about half a minute or so and he is not unconscious.

Since the first "convulsive attack" in July, 1903, the patient has been more or less peculiar in his talk. It was noted that his memory was defective; for he would repeat himself a great deal. To his wife his perception seemed slow and dull. The patient did not realize what he ought to do. He was often apathetic and at other times irritable. His wife noted that he was nervous and could not sit still. She also remarked that he was "kind of childish in his ways—funny notions to do things which would cost a mint of money." He was easily persuaded out of his notions. This represented a marked change in his character. In general his mental condition was one of dullness and slowness.

His wife never saw a so-called smell attack which was followed by a sinking attack; but she thinks the so-called convulsive attacks of later days are attacks of the same character. The patient himself describes the smell attacks by saying: "I could not help myself fainting away." In these early summer attacks he would recover in a few minutes and resume his work. At this time and later in the fall of 1903 he had a strong tendency to go to sleep. He could fall over and go to sleep almost anywhere, and sleep was so deep that he could not be awakened readily. The smell attacks, as before stated, left him in the summer of 1902 to be followed by the convulsive attacks which began in the summer of 1903. He quit work in June, 1903, on account of his headaches, weak spells, and mental condition. Long before he quit work the men in the mill, noticing that he was not himself, had kept a watch over him. It was felt that his mental condition was below par and that he had become untrustworthy and unreliable.

Last January the eyes were examined by Dr. Stieren, who discovered double optic neuritis.

In his attacks he would become limp on the right side. There was some jerking and twitching and very marked and complete or nearly complete loss of consciousness for the time. The patient has never vomited. He has had some impairment of hearing in both ears, the right being more defective than the left. About February 10 nearly a tablespoonful of hard, cheesy material, very offensive in odor, came from the right nostril. Immediately afterward the headache was greatly relieved and the patient's mental condition seemed much clearer. Just before this incident the patient's mental condition had been particularly dull, almost stuporous.

The patient's mental condition is one of sluggishness and apathy, with dullness of perception. Hearing is impaired in both ears, more marked in the right than the left. Vision is greatly reduced, the impairment being much more marked in the right eye than in the left eye. With the right he counts fingers with difficulty. He sees with the left better. He is unable to recognize the largest letter on the test card. He has a high grade of double optic

neuritis. The pupils are equal and respond to light fairly well, the right more than the left. The sense of smell is very deficient. It is doubtful whether he can perceive odors at all in the right nose. There appears to be no proper paralysis except a slight internal squint in the right eye. Sensation appears normal. Stereognostic sense is normal.

Dr. Day illuminated the sinus and thoroughly explored the nose. He was unable to discover pus or any evidence of sinus trouble—indeed, nothing abnormal. He ventured the suggestion that probably the gush of pus which occurred on February 10 was due to frontal sinus disease which cured itself; that such sinus disease may have been entirely intercurrent and independent of the main disease from which the patient suffered. In the light of subsequent events it would appear that Dr. Day's suggestion constituted the correct explanation for the gush of pus, for no relation between it and the large tumor which was subsequently found at the autopsy, located deep down in the brain, could be made out.

The headaches, optic neuritis, smell, or convulsive or fainting attacks, together with the mental changes, and the slow onset appeared to point pretty clearly to an intracranial growth; although there was just a little suspicion, on account of the discharge from the nose (February 10), that the lesion might be an abscess.

As to the location, the symptoms did not appear to point clearly to any one place, but the fact that the smell attacks came early, and that the mental changes appeared to be such as have been described by various authors as occurring in lesions of the frontal lobe, and that there was loss of smell in the right side made it seem mostly likely to Dr. Moyer and I that the tumor was located in the right frontal lobe involving the olfactory nerve by pressure. We accordingly asked Dr. R. W. Stewart to operate on this region of the brain for the relief of the tumor or abscess or as a decompressive operation.

Dr. Stewart operated on April 30, removing a large bone flap over the right frontal region which exposed the base of the skull, and thoroughly explored the brain. No tumor or abscess was found, the bone appeared to be perfectly healthy. There was an extraordinary amount of bulging, apparently indicating increased intracranial pressure. I may say at this point that even had there been no prospect of finding a tumor in the operation, trepanning seemed desirable for the relief of the severe headaches and optic neuritis. The patient was greatly relieved of headaches and optic neuritis, and his mental condition was greatly improved after the operation.

When I saw the patient, three months later, he was free from headaches; his eyesight had greatly improved, and he was much brighter mentally. He had no fits or sinking spells since the operation. There was bulging over the right frontal region. Gentle pressure here showed the protruding mass to be soft and not tense. The patient showed no motor or sensory symptoms.

I now lost sight of the patient. He died on August 20. On August 28 I was invited by Dr. Stieren to examine with him and Dr. Moyer the brain of the patient, which had been removed about a week previously. I learned from Dr. Stieren that the patient had been staying at the Home for Incurables for several months past. There he had been dull and more or less apathetic and had suffered convulsions from time to time. He never became hemiplegic or in any other way paralyzed. I was informed that the relief from headache and optic neuritis was maintained for a long time.

The right hemisphere of the brain showed a tumor about the size of a tangerine orange, apparently springing from the basal ganglia, more especially the optic thalamus, and with attachments to the fornix. The tumor grew in an upward direction into the ventricle. It appeared soft, dark in color, and the portion extending into the ventricle was quite free and appeared as a teat-like projection. The tumor appeared to extend in a lateral direction from almost the median line to within about 4 cm. of the cortex on the outer side. Nowhere did it appear to come in contact with or involve the cortex, unless possibly at the base, which had not yet been incised.

The tumor was shown in the antero-posterior section which had been made by Dr. Stieren. A report of this case has been made by Dr. Stieren in another connection with several other cases to illustrate the great relief of optic neuritis which may follow a decompressive operation.

The specimen was given to Dr. F. Proescher, Pathologist to the Allegheny General Hospital, who furnished the following report of his examination of it:

"The microscopic examination of those parts of the brain having, microscopically, the most alterations, reveals the areas in question to consist of rather closely lying cell masses, round or oval and rich in chromatin. The cell masses, viewed under the moderate power lens, show striking differences in respect to size. Between them but sparingly, lies a strand-like framework containing scattered hemorrhages of larger or smaller sizes, and many blood capillaries. The smaller celled area merges without sharp demarkations into the normal brain substance. Under a higher power lens, one sees readily that the above described oval cells differ from each other very considerably in size and shape. The majority of the cells are from three to five times as large as a normal glia cell. One can see only a few cells which resemble the type of the normal glia cell, they being, however, almost entirely protoplasm-free but very rich in chromatin. The remaining cell masses are mostly round or oval; some, however, are oblong. The chromatin framework consists of two or three chromatin granules, around which are implanted in a radial manner, but irregularly, fine chromatin. In isolated places is recognizable an outer very wide protoplasmic zone, the cells of which remind one, by their makeup, of ganglion cells. The strand-like intercellular substance is seen under higher power, to be composed of finer strands which can be followed out through long distances as continuous bundles. Isolated branches are seen to run out even as far as the large glia-celled outer zone, which is rich in protoplasm, as above described. The strands arise in a bipolar fashion.

"*Microscopic Diagnosis:* Glioma, poor in cells."

Remarks.—The chief points of interest in this case are: (1) The problem in localization. (2) The complicating incident of discharge of pus from right nostril. (3) The great relief of headache and optic neuritis which followed operation. (4) The non-appearance of hemiplegia in the case of a tumor the size of a tangerine orange growing from the basal ganglia.

As mentioned in the body of the article, the mental symptoms, dullness of perception, sluggishness,

forgetfulness, irritability, the smell attacks, and the sinking attacks seemed very strongly to indicate that the lesion was located in the frontal lobe. The evidence pointed strongly to the lesion being a tumor, although the gush of pus from the right nostril for a time seemed to cast a doubt on this conclusion and made it seem possible that it might be an abscess. The explanation offered by Dr. Day soon after the gush occurred, that it might have been due to an independent affection, a frontal sinus disease which had cured itself, now appears the correct one.

The case affords another illustration of the great value of trepanning operations for relieving headaches, optic neuritis, and mental lethargy, due to a brain tumor. Although the tumor was not properly localized, it may be said that hardly anything better could have been done for the relief of the symptoms which it produced. Of course, had its situation been exactly known trepanning the bone in the temporal region would have been better, as we might have there had less cerebral hernia. Because the patient has to die subsequently is certainly no reason why we should withhold from him the relief of a decompressive operation; and I have no sympathy whatever with the view that because permanent relief cannot be given it is useless to attempt to relieve the patient for a time.

The absence of hemiplegia with a tumor situated as this one was, and considering its size, is perhaps the most interesting feature of the case. With our present light it would appear to me that it would have been well-nigh impossible to have localized this tumor. Indeed, the absence of hemiplegia and all other forms of paralysis was one thing which made me, in my endeavors to locate the growth, look outside the motor area altogether. Indications did not point to the base of the brain. There was no cranial nerve involvement, and the cerebellum was not indicated by the symptoms as the seat of the lesion. This negative evidence with the positive, which seemed to point to the frontal lobe, led to the diagnosis of a tumor in this region.

Westinghouse Building.

THE DIAGNOSIS OF TRICUSPID STENOSIS;

REPORT OF CASE WITH TRACINGS.*

By DAVID FELBERBAUM, M.D.,

New York,

House Physician of Montefiore Home.

Of all the vavular diseases of the heart, the rarest and most difficult to diagnose is tricuspid stenosis. As a matter of fact, with but few exceptions the condition is generally first discovered as an accidental finding on the autopsy table. It is therefore self-evident that many cases are unrecognized which I am sure could be discovered were graphic methods more widely employed; certainly many cases that do not come to necropsy would be correctly diagnosed.

This condition may be either congenital or acquired. The latter only interests us, because the subjects of the congenital variety die early in life. It has been found almost four times more frequently in women than in men, and mainly in adults. Leudet[1] collected 114 autopsies of tricupsid stenosis, of which 11 affected the tricuspid valve alone; 3 were cases of stenosis of the tricuspid and pulmonary orifices; 1 was a case of stenosis of the tricuspid, mitral, and pulmonary valves; 21 were cases of stenosis of the tricuspid, mitral, and aortic valves; 78 were cases of stenosis of the tricuspid and mitral valves.

In 1897 Herrick[2] added 40 cases to Leudet's collection, 138 or 90 per cent. being combined with mitral stenosis. In only twelve cases did tricuspid stenosis occur alone. Newton Pitt[3] found 87 cases of tricuspid stenosis in 12,000 autopsies occurring during a period of 26 years. F. W. Griffith[4] examining Leudet's tabulation claims that in all probability only two of the eleven cases reported by Leudet as confined to the tricuspid valves were unassociated with lesions of other valves.

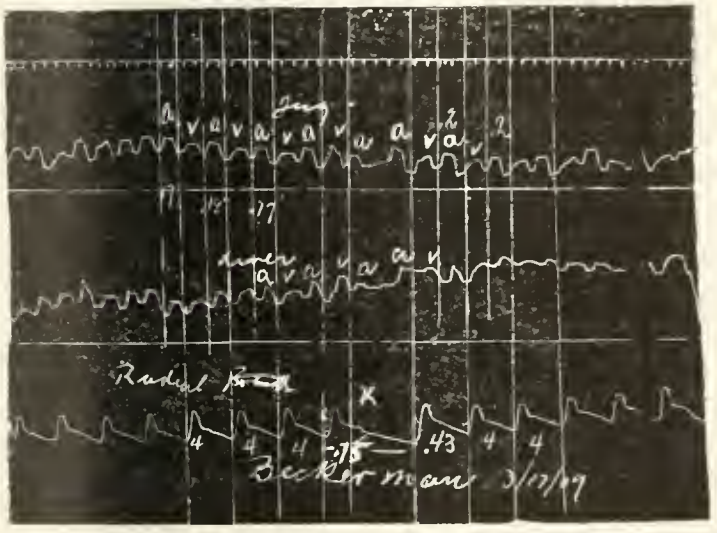

Fig. 1.—The time notches indicate 1/10 second; *a*, auricular wave; *v*, ventricular wave; at *x* is seen an extra systole of ventricular origin.

The above statistics give an idea of the rarity of this valvular affection, and show in particular how unusual it is as an isolated pathological condition. They also account for the fact that tricuspid stenosis has hardly ever been recognized during life; "since the murmur to which it gives rise is identical in time and quality and nearly in position with that of mitral stenosis." Recognizing these facts, all authorities agree that the diagnosis is rarely possible, and mention the condition more as a curiosity. The only suggestive signs referred to are a presystolic murmur limited to the ensiform, and marked enlargement of the heart to the right, but the characteristic murmur is present in but few cases. Mackenzie[5] in many observations has heard this characteristic murmur only three times, this being probably due to the fact that tricuspid stenosis occurs associated with mitral stenosis in between 87 to 90 per cent. of cases, the one overshadowing the other.

To James Mackenzie, who has done so much in advancing our knowledge of heart disturbances, is due the credit of first calling attention to the peculiar jugular and liver pulses in tricuspid stenosis. In his book "The Study of the Pulse" he calls attention to the fact that an auricular type of venous liver pulse is probably diagnostic of tri-

*Read before the alumni meeting of the Montefiore Home, February 28, 1909.

cuspid stenosis. Venous pulsations appear in two types, one the negative, according to the older literature, and the other the positive or better, as Mackenzie designates them, the auricular venous pulse and ventricular venous pulse, referring to their physiological origin. The negative venous pulse

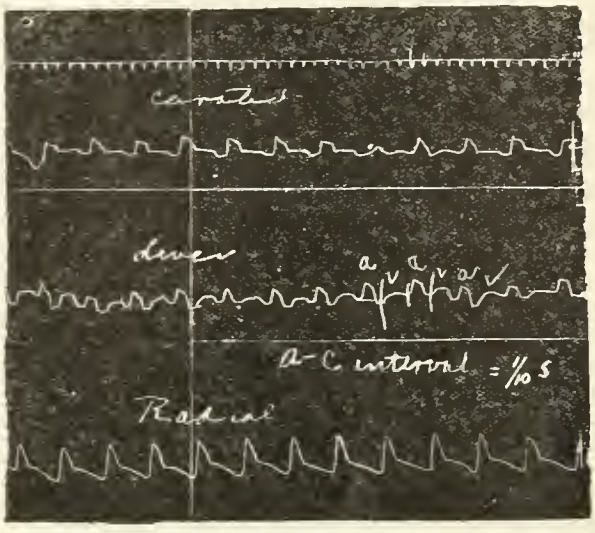

FIG. 2.—Tracing, showing carotid pulse and liver pulse compared with the radial.

is found in a great many individuals, and may be normal or pathological, while the positive venous pulse is always pathological and, as is well known, means tricuspid regurgitation, distention, and paralysis of the auricles.

The negative or auricular venous pulse consists usually of three waves, referred to as *a*, *c*, and *v* waves; the first due to contraction of the auricles; the second, according to Mackenzie, due to impact of the carotid pulse, while others claim it is due to the swaying back of the tricuspid segments; and the third produced by the activity of the ventricle. The wave *c* often is absent, depending on certain conditions not necessary to discuss here. Mackenzie, who was one of the pioneers in adopting polygraphic methods in clinical investigation of circulatory disturbances, made extensive studies of the venous pulse and especially of the liver pulsations. The only type of liver pulse known when he first took up his investigations was the positive or ventricular variety of pulsation, due to the regurgitation of blood through a widely open incompetent tricuspid valve. But in 1880 he observed a case of mitral disease in which the liver pulse did not correspond to the usual type, *i.e.* a positive pulse. At first he did not know what to make out of this. When compared to the tracing of the jugular taken simultaneously it corresponded exactly, there being present a presystolic or *a* wave and a systolic or *v* wave. (See tracing 1.) What was the meaning of this? Mackenzie's explanation proved correct, namely, that there was an hypertrophy of the right auricle which was strong enough to propagate a wave into the vena cava and liver producing the pulsations. He wisely decided that this hypertrophy was the result of some obstruction, and following the analogy of mitral stenosis, he came to the conclusion that there was a stenosis of the tricuspid valve. This train of deduction proved to be correct when the patient came to autopsy. In all he has obtained such tracings twenty times, and in seven of these he has had autopsies, all showing a tricuspid stenosis. He has therefore advanced the statement that an auricular liver pulse is probably diagnostic of tricuspid stenosis. He refers to two exceptions to this rule; one, a case of pericardial effusion reported by Volhard,[6] and two, a case of adherent pericarditis reported by Wenckenbach,[7] both showing an auricular jugular and liver pulse. One other important fact he had made clear, which, by the way, is contrary to the usual statements in textbooks, and that is that the prognosis is not at all grave. He has followed his patients for long periods of years and all have kept up in good condition. This observation has also been made by Volhard, who draws particular attention to the compensatory effect of tricuspid stenosis to mitral stenosis.

The symptomatology shows nothing characteristic except the murmur, which, as has been indicated above, in the majority of instances is missing. Subjectively the patient has the usual symptoms found in endocarditis. Some authors speak of cyanosis as a distinctive feature, but this is only in the later stages, when tricuspid incompetency and paralysis of the auricle supervene. The liver is always enlarged and pulsations are frequently recognizable only by graphic means, and therefore as a rule escape notice. The jugular always pulsates visibly, and in one case noted by Mackenzie the right auricle was so hypertrophied that it sent back a wave with such force into the jugular as to close its valve with a snap. The case which I wish to report is unique in many respects.

J. B., 39 years old, admitted February 3, 1909, native of Russia, bricklayer by occupation. Mother suffered from rheumatism, otherwise the family history is negative. He has had measles. He was always strong and healthy, and served in the Rus-

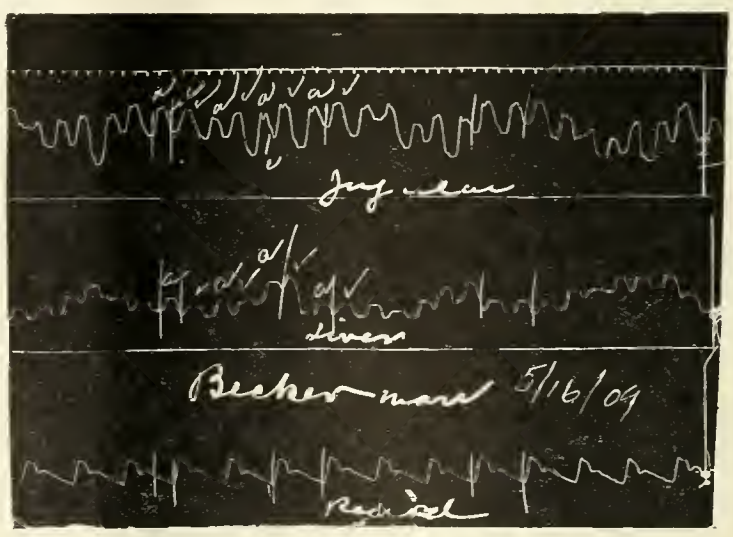

FIG. 3.—Tracing, showing jugular pulse and liver pulse compared with the radial

sian army. Fifteen years ago he fell two stories, and since then has been subject to attacks of vertigo, lasting 5 or 10 minutes. Occasionally he would vomit. No loss of consciousness. For five years past the right foot becomes at times numb and insensible. There is no pain or paralysis. These spells come on once a month, and last about 15

minutes. He is married, and is the father of four children, his wife having had one miscarriage in her third pregnancy. He was accustomed to smoke about 12 cigarettes a day. Took whiskey before breakfast and during the day. At times would take up to six glasses of beer also Sexually moderate. Denies all venereal diseases.

Two years ago he had to stop work because of progressively increasing shortness of breath. Dyspnea would develop upon the least exertion. He frequently has palpitation. No swelling of legs. Never was cyanotic. He has developed hemorrhoids, and a few months ago coughed up some blood. At present he complains of weakness. He is well nourished; the left pupil is a little larger than the right, but both react to light well. There is marked engorgement of the jugular, especially brought out on lying down when all the veins in the neck stand out prominently and the entire region above the clavicles pulsates in an undulatory manner. The chest is of emphysematous build.

The apex beat is not visible or palpable except after exertion, when it is felt in the fifth space, about half an inch to the left of the midclavicular line, and a distinct short thrill is palpable at the apex of the ensiform. The right border is found on percussion in the fourth space two inches from the middle line, the left border in the fifth space five inches from the middle line. On auscultation, a very peculiar murmur is audible. It is strongest and most prolonged over the ensiform, and is of a rough, grinding character. It seems to begin at the end of diastole, but is most evident during systole. As the stethoscope is carried to the left it becomes more blowing, soft, and systolic in character, disappearing at about the anterior axillary line. Pulse is regular, small, slightly sclerotic, systolic pressure 140, diastolic 80 mm. (Erlanger apparatus.)

The liver is palpable midway between the free border of the ribs and the umbilicus. The spleen is not felt. On careful inspection of the right hypochondrium a fine undulation is observed.

Numerous tracings were taken after his admission into the Home, but unfortunately the apex beat could not be registered on account of the emphysematous lung and the thickness of the chest wall. These tracings constantly show that the liver pulse consists of two waves. One is presystolic in time, the other occurring during the ventricular systole. On one occasion extra systoles of ventricular type were present (X—Fig 1). When the jugular is taken simultaneously above the liver pulse, both correspond. This, then, is exactly what Mackenzie found in his cases of tricuspid stenosis. In the neck the venous pulsations were so extensive that the carotid was with difficulty obtained, a further evidence of some powerful *vis a tergo*. (Tracing No. 2.)

In seeking for the etiology we were at a loss as the anamnesis furnished no clue. Dr. Kaplan, our pathologist, made three Wassermann tests, all of which proved positive, likewise the Noguchi modification. Whether the endocarditis is of syphilitic origin remains an open question, but, taking into account the significance of the Wassermann reaction, we are employing the usual antispecific treatment.

In conclusion I wish to draw again attention to the salient points:

(1) An auricular type of liver pulse occurring in a case of endocarditis is diagnostic of a complicating stenosis of the tricuspid orifice.

(2) Stenosis of the tricuspid orifice can hardly ever be recognized by the usual clinical means of investigation; when graphic methods are employed its presence can be determined positively.

In reference to my case, the points to be noted are:

(1) The tracings obtained prove conclusively the presence of a tricuspid stenosis. Most likely there is also a mitral lesion, because of the systolic murmur transmitted to the left and the extensive enlargement of the heart to the left.

(2) The excellent general condition and the slight discomfort experienced by the patient exemplifies the observation of Mackenzie and Volhard.

(3) A probable syphilitic etiology.

REPORT OF AN UNUSUALLY INTRACTABLE CASE OF IRITIS WITH SOME REMARKS ON THE ETIOLOGY OF IRITIS.*

By WM. CAMPBELL POSEY, M.D.,
PHILADELPHIA, PA.

I am instigated to report this case before the Society not only because it illustrates the tenacity with which inflammation of the iris may, under certain conditions, repeat itself again and again, despite all precautionary measures, but also to demonstrate the impossibility of avoiding post synechia in such cases, even when treatment is administered in the earliest stages and actively persisted in during the entire inflammatory process.

The patient, the subject of this paper, a professional man in middle life, first consulted me in the summer of 1902, on account of a severe attack of keratoiritis in the right eye. Both eyes had been the seat of a mild attack of conjunctivitis three years before, but the present involvement of the right eye was the first serious ocular inflammation from which he had suffered. It was elicited that the patient had had more or less muscular rheumatism since childhood, but in 1892 some of the joints became affected six months after an attack of urethral gonorrhea. A gleety discharge persisted for several months after the inauguration of the urethritis, and the inflammation in the joints was severe for a time, but both subsided under careful treatment, the patient marrying soon after, and his wife giving birth at the end of a year to a healthy child. Another child has since been born, and both offspring and the mother as well are the pictures of health and give no evidence of having

*Read at meeting of Wills Eye Hospital Association, May 3, 1909.

suffered from the systemic poisoning of the father. The patient, too, upon the whole, has enjoyed good health, notwithstanding that he has suffered somewhat from rheumatism, or rather rheumatic pains, usually in the back or hips, but never in the joints. Though at odd times small gouty concretions have appeared in various parts of his body, these would vanish as mysteriously as they had appeared, after months or years, without ever exhibiting any inflammatory signs. At no time since his marriage has he been compelled to take to his bed with fever. He has never suffered from nasal catarrh and various examinations which have been made by a competent rhinologist from time to time have never showed any sinus involvement. His father is gouty and of gouty ancestry. His mother died years ago of heart disease.

When first seen in the summer of 1902, the right eye was the seat of an intense keratoiritis, which persisted with great severity for three weeks, finally leaving the eye with normal vision but with a tag of post synechia below. Six months later (February, 1903) iritis again appeared in the same eye, but disappeared under two weeks' treatment. Both eyes were then free from inflammation for a year, despite rather severe rheumatic pains in the hip, which necessitated his visiting a well-known hydropathic resort before he was relieved. In May of the following year, the left eye became violently inflamed, the iritis being controlled only after six weeks of active treatment. A mild recurrence followed two months later in the same eye and another a year later, which persisted three weeks. During the next fourteen months the ocular inflammations were less serious, a shallow ulcer occurring on the cornea of the left eye and a stye or two on the lids of both, and numerous small chalky infarcts in the conjunctiva of both eyes. In March of 1907, the left eye suffered another attack of iritis, which was followed two weeks later by an involvement of the same membrane in the fellow eye. The next eighteen months passed without ocular complications, but in January of this year, a mild attack of iritis appeared in the left eye and was followed in ten days by an involvement of the right, a recrudescence of the symptoms in the left eye some days later, and finally, three weeks after the initial symptoms had appeared in the left eye, the right eye became reinvolved with an inflammation of unusual severity, from which it is but now recovering.

This is a very brief account of the various attacks of ocular inflammation which have occurred in this unfortunate individual and describes very imperfectly what he has endured. The actual suffering at no time, however, has been very great, for the inflammation has always assumed a serious rather than a plastic type. Upon several occasions the patient has retired for the night with a pupil almost fully dilated and with good vision, to awaken in the morning with vision almost entirely absent, with a contracted pupil and with the anterior chamber deepened and completely filled with a mass of semi-translucent exudate, as though the somewhat turbid crystalline lens had slipped forward and was crowding the anterior chamber. Following the last attack in the right eye, the vitreous was filled with opacities, indicating the simultaneous involvement of the ciliary body and adjacent choroid. Locally the inflammation was controlled in all of the attacks, by atropine in strengths varying from four to eight grains to the ounce, by dionine of from two to ten per cent. solution in strength, by the continuous application of moist hot compresses administered by competent nurses day and night for weeks at a time, and by leeching at the commencement of the attack. In most instances massive doses of salicylate of soda were administered in the beginning of the iritis, in combination with enunctions of mercury, while later potassium iodide was substituted in doses rapidly increasing to fifty grains three times daily. Dovers Powder was also found useful several times a week, to provoke diaphoresis, while the patient was encouraged to drink a large quantity of water and his diet was carefully regulated. The bowels were kept open by salines. Antigonococcic serum was never employed, as I was averse to essaying in his case, any but the most conservative and approved plan of treatment.

Notwithstanding the frequency and virulency of the inflammatory processes to which both eyes have been subjected, vision is normal in each, though the presence of synechia in both eyes, with a commencing capsular degeneration where the iris is in contact with the lens, suggests that later lenticular changes may interfere more or less with visual acuity. The future, therefore, is more or less doubtful, for ten years must still elapse before the age of sixty years is attained, the period at which the masculine sexual functions are commonly supposed to generally undergo a change, and when some authorities have remarked that attacks of iritis in males cease to occur.

Should vision markedly deteriorate, or should other complications from the synechia manifest themselves, iridectomy will be advised, as the influence of this operation in preventing recurrences of iritis, and upon the condition of the eyes in general, in cases of long standing synechia has been generally recognized. General hygienic and dietetic measures will of course be enforced and every effort made to hold the rheumatism in abeyance, since it would appear that gonorrheal rheumatism has been the etiological factor at work in the production of the iritis in this case.

Gonorrheal iritis has long been recognized as a definite form of ocular disease; indeed Brodie described this variety of iritis as early as 1834, and Mackenzie and other early British ophthalmologists were well acquainted with it. In the majority of cases, perhaps, the last attack of gonorrhea occurs some years previous to the iritis, and in most instances there is no attending arthritis. As Higgins has well said,[1] "the probability is that in many men who have had gonorrhea frequently there is left for any number of years in some part of the urinogenital apparatus a very much attenuated virus, which gives no trouble locally, but from time to time becomes more active, and though still setting up no local irritation, is capable after absorption of causing inflammation in synovial membranes or in the iris; in fact, it looks almost as if the iris becomes on occasion an excretory organ and tries to eliminate the poison, receiving considerable damage to itself in the attempt."

Iritis, arthritis, and endocarditis may occur independently or simultaneously, the association being accidental and not necessary, the gonorrheal poison, as Lawford[2] has stated, having like that of most infectious diseases, certain seats of election in the tissues, and it is in no way surprising that evidences of the existence and activity of the poison should

appear in several such tissues at or about the same time. As the same author has also pointed out, both gonorrheal arthritis and gonorrheal iritis have certain points in common. They are both prone to relapse and leave behind them an apparent vulnerability of tissues which may and often does persist for a very long period. An eye which has been attacked by gonorrheal iritis and a knee-joint which has been the seat of gonorrheal arthritis, are liable to recurrences of inflammation without any fresh gonorrheal infection. This liability may last for years. There must, however, be a personal element or an idiosyncrasy in those who suffer, because the proportion of persons who have arthritis and iritis to those who have had gonorrhea is very small.

The late John Griffith[3] attached great importance to gonorrhea as a causative factor in iritis, and thought that the ocular inflammation was not only liable to occur as a complication, but also as a sequel of gonorrhea, the ocular manifestation of constitutional gonorrhea appearing, in his experience, many years after the complete disappearance of the initial local inflammation. Though in some of his cases it was impossible to exclude a very protracted gleet, in the greater number there was every reason to believe that the urethritis was a thing of the past, and that a considerable period had elapsed since the final disappearance of the gonorrhea. He did not imply that the poison of gonorrhea in the system is the precipitating cause of the iritis, for many agents such as exposure may determine the attack, owing to the reduced tissue resistance of the body wrought by the gonorrheal poison, a feature paralleled to that of a gumma in syphilis.

To prove the existence of gonorrheal iritis, Griffith thought the following conditions must be present: 1. An attack of iritis, prone to recur; 2, gonorrhea at some antecedent date; 3, rheumatic pains, either arthritic, muscular, or facial, developing subsequent to the urethritis; 4, exclusion of other causes of spontaneous iritis. Gout and chronic rheumatism, as well as gonorrhea, have long been recognized as capable of giving rise to iritis, indeed no less an authority than our colleague, the late Dr. William F. Norris, averred that the majority of cases of iritis which he had been called upon to treat were due to that cause. A number of observers, however, are very skeptical of rheumatism *per se* evoking iritis, and believe that a great number of the so-called case of rheumatic iritis are really gonorrheal in origin. My own experience teaches that iritis dependent upon rheumatism does frequently occur, but I am also convinced that a gonorrheal element is often present in a large number of rheumatic cases, and that where this is the case the disease assumes a very virulent type. It should be remembered, however, as pointed out by Berkely Hall and Jonathan Hutchinson some years ago, that those with a gouty constitution are more apt than others, other things being equal, to suffer from gonorrheal iritis, as they observed that people who had gonorrheal arthritis were frequently the descendants of those who had suffered from undoubted attacks of gout. The proof of this observation has recently been demonstrated by Treacher Collins, for of one hundred cases in which he and Silcock inquired into the constitutional history of primary iritis, fourteen occurred in connection with gonorrheal arthritis, and of fifteen cases of gonorrheal arthritis who had iritis Collins found an undoubted family history of gout in five of them. In such cases he thought it likely that the iritis might be attributable to inherited gout, rather than to the gonorrheal attack. The case under discussion seems to bear witness to the truth of Hall and Hutchinson's observation, as he inherited a gouty tendency from his father, and had in addition suffered more or less from so-called muscular rheumatism, before the urethritis precipitated the arthritis.

Of one hundred and fifty-nine cases of iritis at St. Bartholomew's Hospital, fifty-six adult males gave no evidence of syphilis. Of these twenty-eight, or 50 per cent., had suffered from gonorrhea. Of the twenty-eight, twenty-six had a history of arthritis, past or present. Finally, in thirteen of these twenty-six, the association of gonorrheal arthritis and iritis was so close as to justify the term "gonorrheal iritis." This was equal to 8 per cent. of gonorrheal cases out of one hundred and fifty-nine cases of primary iritis. In another series of forty severe cases of gonorrheal arthritis, eight were women without iritis, and thirty-two men, of whom five (15.6 per cent.) had iritis as a complication.

Beaumont, living in Bath, England, sees a large number of men of good health with iritis accompanied or preceded by rheumatism in the joints or lower limbs. They confess to a gonorrhea, many months or years before the rheumatism, but are sure there is no relationship of a parental nature between the gonorrhea and the iritis. Iritis occurs but seldom in the rheumatoid arthritis cases which come to Bath, and Beaumont explains this by the suggestion that iritis is a symptom of the earlier stages of the disease, whereas the patients who seek relief in Bath are in the later stages. My own experience is not in accord with this, as I have treated a number of most intractable cases of iritis in advanced cases of rheumatoid arthritis.

Beaumont observed several cases in quite aged women, the inmates of homes, in whom any complicating gonorrheal agency, if present, must have been extremely remote.

In concluding these few remarks upon the etiology of iritis, it should be remarked that all reference to syphilis, tuberculosis, and other possible causes of iritis have been purposely omitted, as it has not been my intention to treat exhaustively of the etiology of iritis, but rather to outline the influence of gonorrhea and gout in the production of this disease, as exemplified in the case under discussion.

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

By LEWIS M. GAINES, A.B., M.D.,

ATLANTA, GA.

ATTENDING PHYSICIAN ATLANTA ANTI-TUBERCULOSIS ASSOCIATION DISPENSARY; ATTENDING PHYSICIAN PRESBYTERIAN HOSPITAL; CHIEF MEDICAL CLINIC ATLANTA SCHOOL OF MEDICINE; ASSOC. MEDICAL DIRECTOR PEACHTREE HEIGHTS SANATORIUM FOR THE TREATMENT OF TUBERCULOSIS.

During the past decade an enormous literature has developed on all phases of tuberculosis. The discussion of early diagnosis has justly occupied a prominent position in all that has been written. And

*Read before the Fifth District Medical Society, College Park, Ga., May 25, 1909.

yet, despite this constant repetition, considerable misapprehension still exists concerning the early diagnosis of this dread disease. In this paper I desire as far as possible to give only practical suggestions culled from personal experience with the disease arising from daily contact with tuberculous patients.

Allow me to indicate in summarized form the classification of pulmonary tuberculosis which has been universally adopted, and which is recommended by the National Association for the Study and Prevention of Tuberculosis. 1. Incipient stage. During this stage tubercles are forming in the lung, and there is very slight constitutional disturbance. 2. Stage of softening, often known as the second stage, during which time the lung tissue is breaking down, there is considerable expectoration, and fairly marked constitutional disturbance, due principally to mixed infection. 3. Stage of excavation, or far-advanced stage, in which there is usually cavity formation and all the constitutional earmarks of consumption.

I desire in this paper to deal only with the practical points which will enable one to make a diagnosis during the incipient stage, the only time when there is a bright prospect for a cure.

In this, as in all diseases, we base our diagnosis on (1) symptoms, (2) physical signs.

Symptoms of Incipient Pulmonary Tuberculosis.—Under this head I shall include the past history as well as the history of the present illness. The first essential point to be inquired into is the opportunity for infection from birth to the time of interrogation. This opportunity may come from residing in the same house with a tuberculous patient, usually parent or other relative, or from close association in office or store with a patient, or from living in rooms or houses previously occupied by tuberculous victims. I believe the ordinary city boarding house to be a fruitful source of infection to young men and women whose limited incomes drive them to seek cheap lodging. Such cases are being constantly brought to my attention. A few weeks ago I was called to see a thirteen-year-old girl who was dying of the disease. The mother could think of no way in which the child had been exposed to infection. Close questioning developed the fact that nine years previously the family had moved into their present home, in which a consumptive had died a few months before. The seeds had been well sown, and during the stress of puberty the organism weakened and the disease asserted itself. I feel assured that a very large proportion of cases developing near the age of puberty have had dormant bacilli in their glandular systems since early childhood—planted there by intimate contact with a careless case, and not transmitted by the mysteries of heredity. A second point of considerable importance in the history is the previous occurrence of pleurisy, perhaps years before. Statistics show conclusively that a large proportion of these pleuritic cases ultimately develop tuberculosis.

Briefly stated, the early symptoms proper, which afford diagnostic data, are as follows: (1) Gradual loss of weight not attributable to other causes. This symptom taken alone, and particularly in the South, is of small moment, but when associated with one or more other symptoms is quite suggestive. (2) Gradual decline of strength, manifesting itself more by a languor most marked in the afternoons and a tendency to tire easily. (3) Slightly dry cough, with often no expectoration, or at best very slight clear sputum, in which tubercle bacilli are comparatively rarely found. There may be no actual cough, but rather a tracheal irritation, shown by clearing of the throat. This I have observed in quite a number of cases. The cough at this stage is usually a very subsidiary manifestation, and occasions practically no discomfort. (4) Hemoptysis. While this symptom undoubtedly does occur in the true incipient cases, it is very frequently present first in the second stage. Many eminent students of the disease now consider it an evidence of softening. However, it is *the* early symptom which most alarms the patient, and thus causes him to consult a physician without delay. Hence it is frequently a blessing in disguise. If it can be established that the bleeding comes from the lungs, there can be comparatively little doubt as to the presence of tuberculosis. One has to rule out other sources. Some months ago a well built young man came to me, giving a history of spitting up several mouthfuls of blood on the previous day. I could find no evidence of tuberculosis on physical examination. At my request Dr. R. R. Daly examined the nose and found an ulcer, fully accounting for the bleeding. (5) Disturbances of temperature and pulse. These are exceedingly valuable diagnostic data. But to be valuable some trouble must be taken to ascertain them accurately. Both pulse and temperature should be charted for a period of at least three days, preferably every two hours. In a considerable percentage of early cases an afternoon rise of one or two degrees of fever will be observed, and an increased pulse rate of ten to twenty or more beats above normal while the patient is at rest. One of the most characteristic effects of the pure tuberculous toxine is the delicate pivoting of the pulse rate. The least excitement, the least exertion will cause tachycardia, which may be perceptible to the patient but frequently only to the physician. A kindred manifestation is the occurrence of erethism, which I have several times observed in young persons.

In addition to the frequent symptoms just detailed, various other disturbances are often observed, particularly persistent digestive disturbances, often associated with anemia. It is also to be borne in mind that in so insidious a disease as tuberculosis some patients may exhibit only a few symptoms in such a mild form that they protest against an examination as a useless procedure, while others may have all the symptoms in severe form. Between these two extremes lie all grades of manifestations to trap the unwary diagnostician.

It is a widespread belief that many cases of tuberculosis begin with a neglected cold. The true beginning of the disease antedates by many weeks or months the so-called cold which really marks the onset of secondary infection, and hence of such prominent symptoms that the attention of the patient is sharply drawn to his condition. It should be our endeavor to make the diagnosis long before the "neglected cold" stage. In order to do this the laity must be instructed what the early symptoms are so they may present themselves for examination early in their disease. Happily, this work of public instruction is now going on with great vigor.

Physical Signs of Early Pulmonary Tuberculosis.—I wish to urge, as introductory to this part of the discussion, that only the most careful and painstaking examination of the bared chest will suffice, and that the stethoscope is a necessity. It is not my purpose to weary you with a hackneyed recital of the

early physical signs which are set down in classified form, and stated pretty much alike in all the text-books. I desire, rather, to briefly give the leading points which I have found to be of most practical value to me.

(1) On inspection I have found the most constant and positive sign to be scapular atrophy. In quite a number of early cases in which the movements and configuration of the chest were apparently normal a noticeable atrophy, usually unilateral, and corresponding to the affected lung, was readily seen. Needless to say, this sign is only suggestive and valuable only in connection with others.

(2) Apical dullness. I would call attention to the fact that in the vast majority of adults the primary site of tuberculous deposits is in the posterior portion of the apex of the lung about an inch from its summit. Hence in both percussion and auscultation the closest attention should be paid to the supra scapular and interscapular regions. The mistake is frequently made of directing most, if not exclusive, attention to the supra and infraclavicular regions which, as a rule, are involved secondarily. In the very early stages careful percussion will often elicit dullness combined with a sense of resistance which is often more trustworthy than the sound. Over the right apex, particularly in front, the percussion note is normally higher pitched than over the left, but the sense of resistance is lacking. I have found by experience that accurate percussion is a most difficult art to acquire. It only comes with constant and patient practice, but yields exceedingly valuable evidence.

(3) Auscultatory signs. It seems to me that frequently in text-books and in the literature generally hypothetical and confusing statements are made concerning the early audible evidences of tuberculosis. I desire simply to state the methods and signs which serve me best. Both physician and patient should be comfortable and avoid strained and unnatural positions. The patient should be stripped to the waist and placed in a good light, while the physician should be armed with his own well tried and trustworthy stethoscope. "It is to be remembered that the stethoscope, like other instruments of precision, requires constant practice in order that proficiency in its use may be gained. Furthermore, one gets accustomed to his own instrument, which yields him a satisfaction superior to any other. One should borrow or lend a stethoscope with about the same compunction he would a tooth brush. It has been from the infrequent use of an unsuitable or borrowed instrument that all slander of stethoscopes has arisen that I have heard."* After the patient is ready for the examination, he must be taught how to breathe properly, for unless he does little information of value will be obtained. The chest should then be gone over systematically. There are just two things to listen for. The first of these is the occurrence of râles. In the early stage they are usually of the fine, moist variety and sound exactly like hair being rolled between the fingers. Occasionally squeaking or whining sounds are heard. These occur at the end of inspiration, and frequently can be elicited only after causing the patient to cough. I desire to emphasize the value of cough followed by a moderately deep breath as a means of bringing out these sounds. One is confused at times by muscle or other extraneous sounds. If this be the case I have found it helpful to direct the patient to hold his breath until complete silence occurs. The patient then being directed to slowly inspire, the presence or absence of râles can be more definitely determined, as the period of silence puts the auditory apparatus in a more receptive and delicately adjusted attitude, and helps wonderfully in removing confusion.

The second thing to listen for—meanwhile detaching the mind from the question of râles—is the character of the breath sounds. The absolutely essential qualification for success here is a thorough acquaintance with the normal breath sounds over the different areas of the lungs. Then the examination is comparatively simple, as one has only to compare the pitch, duration and intensity of inspiration and expiration. If these three qualities are present equally on inspiration and expiration the breathing is bronchovesicular; if they are most marked on expiration, the breathing is bronchial. If now one is listening over an area where such breathing is not normally present, the inference of consolidation, more or less marked, is obvious. In addition to the above characteristics, there is frequently heard in the earliest stages what must be called harshness, particularly on inspiration. This term has been objected to by many clinicians, but nothing else can define the raucous, roughened sound distinctly different from the smooth, gliding sound of the normal respiratory murmur.

One other point of value is the diminished intensity of both inspiration and expiration over one side of the chest as compared with the other. Unilateral dimunition of the breath sounds is occasionally a well marked early sign.

The Use of Tuberculin in Early Diagnosis.—Time necessitates a very brief notice of this important method, about which so much has been written. In adults the various local reactions give such variable results that I have ceased to rely on them at all. Their principal recommendation, to my mind, is their ease of application, but like most short cuts they are untrustworthy and deceptive. I do believe firmly, however, that in all doubtful nonfebrile cases tuberculin should be injected and the following technique employed: 1. Obtain pulse and temperature from 8 A.M. to 10 P.M. every two hours for at least four days. 2. If both are approximately normal, give hypodermically at the angle of the scapula 0.5 mg. Koch's old tuberculin, and keep the same record of pulse and temperature. 3. If there is no reaction in three to four days either repeat the same dose, if there is a suspicion of a reaction, or administer in the same manner 1.25 mg. if no such suspicion occurs. 4. If there is still no reaction after two to four days, repeat or give 2.5 mg. 5. A still larger quantity may be given if still there is no reaction. Some excellent clinicians give as the fourth dose as much as 10 mg. Personally, I should prefer not to exceed 5 mg. If after the administration outlined no reaction occurs the inference may be safely made that no tuberculosis exists in an active form.

A reaction consists in a rise of one degree F. above the previous maximum before injection, associated with general symptoms of more or less marked constitutional disturbance of one to two days' duration. In addition, there is usually manifested at the point of injection redness and slight swelling. Furthermore, a hyperemia of the infected area in the lung occurs manifested by the appearance of moist râles. The lungs should, therefore, be auscultated all during the time of administration,

*Lewis M. Gaines, M. D.—"Accuracy in Diagnosis of Diseases of the Chest," Trans-Georgia Med. Assoc., 1909.

for it is sometimes possible to perceive the râles before the occurrence of marked general symptoms.

Sputum Examinations.—I desire, finally, to emphasize the unreliability of a negative sputum examination. The continued absence of bacilli is of no value in ruling out the disease. Gerhardt makes the statement: "I know of cases in which the bacilli were not found for months or only in the sixtieth specimen, but when the diagnosis of tuberculosis was established by examination of the chest."

It has been our experience with all stages of cases at the Dispensary of the Atlanta Anti-Tuberculosis Association that only in 62 per cent. were tubercle bacilli found on the first examination. The same is true in other large clinics. Hence one should feel no exultation if bacilli are absent not only once or twice, but even for scores of times. Needless to say, the presence of bacilli is valuable and positive evidence of the existence of active disease, and the examination should invariably be made.

Conclusions.—In dealing with so large and important a subject much must necessarily be omitted from a brief paper. My object has been to state those points which I have found of value, and perhaps to excite a discussion which will prove of practical interest. I venture in closing to draw the following general conclusions: 1. The clinical picture of very early pulmonary tuberculosis is utterly different from what is popularly known as consumption. 2. The symptoms of early tuberculosis are exceedingly insidious, and easily overlooked in a considerable number of cases. The laity particularly should be instructed concerning the nature of these early symptoms, and physicians should be on the alert for them. 3. The physical signs of early tuberculosis are difficult of detection, and necessitate a particularly careful examination. 4. Tuberculin properly and carefully applied is of great value in diagnosing early afebrile cases. 5. The prolonged absence of bacilli from the sputum is of no value in diagnosis.

ON THE ESTIMATION OF THE URINARY AMMONIA, AND A NEW INSTRUMENT FOR ITS RAPID ESTIMATION.

By HENRY R. HARROWER, M.D.,

CHICAGO, ILLINOIS.

The determination of ammonia, although of undoubted diagnostic importance, is practically never carried out as a routine measure, methods at present in general use for this test being not only tedious and complicated, but requiring expensive and cumbersome apparatus suited only to the larger laboratories, not to the physician's office.

"A knowledge of the amount of ammonia present in the urine has an important practical value in many conditions met with in everyday practice.[1] The relation between the urea index and the amount of ammonia is very important, showing, as it very often does, the existence of depraved metabolic conditions, usually isidious in their origin and manifestations, and consequently not appreciated either by physician or patient until irreparable damage has been done.

The average normal percentage of urea varies from 2.25 per cent. to 2.5 per cent., and the total amount excreted in twenty-four hours from 25 to 30 grams, or about 80 per cent. of the total urinary nitrogen. The normal ammonia-content of the urine is about 0.7 gram in twenty-four hours, or only 3 per cent. of the total nitrogen.

In disease the urea is frequently greatly diminished, while the ammonia is correspondingly markedly increased. This, in all probability, is due to the manufacture of an excess of acid substances, causing a condition of acidemia, the body attempting to modify this dangerous condition by neutralizing the acid substances with the ammonium precursors which are ordinarily changed in the liver into urea and so excreted. In this way it will be seen that while the urea output is decreased the amount of ammonium salts is correspondingly increased.

The estimation of these important factors—acidity, urea, and ammonia—must shed much light upon the metabolic functions of the body and offers to the clinician information which may be made of the greatest possible therapeutic value.[2]

Tube for rapid examination of the urinary ammonia; the fine lines marking the degrees have been omitted in the illustration.

Elsewhere[3] I have described a simple instrument for the estimation of the urinary acidity. A slight modification of this instrument will permit of an even more accurate determination of the acidity than before, and also a quick and easy estimation of the amount of ammonia present in the urine.

This instrument consists of a graduated glass tube, and, aside from it and the reagents named, the test requires only an ordinary medicine-dropper: 1. Decinormal sodium hydroxide solution. 2. Phenolphthalein indicator solution (one-half per cent. phenolphthalein in 50 per cent. alcohol). 3. Potassium oxalate (neutral powder or crystals). 4. Commercial formalin which has been diluted with an equal volume of water and rendered faintly alkaline with sodium hydrate, phenolphthalein being used as an indicator.

The test is carried out as here described: The tube is filled to the 10 c.c. mark with urine (poured down the side of the tube to prevent foam). Three drops of the indicator solution are now added, then 3 or 4 grams of potassium oxalate and water exactly to the zero mark. The tube now is closed with the thumb and shaken, then decinormal soda solution added slowly (inverting the tube from time to time) until the fluid in the tube assumes just a faint pink color. The total acidity is now read off in degrees at the level of the fluid in the tube, and is marked down. About 2 or 3 c.c. of the formalin solution is now added, and the level again noted. (It is convenient to add sufficient of this reagent to bring the level to some even mark, which is marked down.) The pink color being discharged by the acids liberated from the ammonia salts by the formalin, decinormal soda solution is again added until the pink color is just regenerated. Each cubic centimeter of decinormal soda solution re-

quired to produce this second reaction represents .00068 gram of ammonia. The amount per cent. is obtained by multiplying by 10, or the per diem figures are easily calculated.

The normal degree of urinary acidity fluctuates between 30 and 40 degrees (each degree representing the amount of decinormal soda required exactly to neutralize 100 c.c. of urine). The normal amount of ammonia is approximately 0.054 per cent., or 0.7 gram in twenty-four hours.

Comparison of a number of tests made with this instrument, and a like number of accurate nitrogen estimations (Kjeldahl), Folin's tests, and Nessler's tests, shows only a comparatively small percentage of error. It is freely admitted that the figures obtained by the use of the ammoniometer are approximate; but it must be remembered that this is also true of all the usual laboratory methods, such as the estimation of urea, albumin, or density. As a matter of fact rarely, if ever, is laboratory work in the physician's office, or even in the physiological laboratory, free from error, and it is not expected that such work is to compare in accuracy with the quantitative work of the analytical chemist or the mineralogist.

In medicine we are perfectly satisfied with comparative results. Approximate figures may be of immense value to the investigator, since the percentage of error in the performance of, say, three tests is always the same, and any fluctuations or variations from a normal figure obtained in the same way are, on the face of it, a reliable indices of the condition causing these variations.

The basic principles of this test for ammonia were described by Malfatti[4] and very favorably discussed by Mathison. It can readily be seen that the more expensive delivery burette, graduated pipette and titrating flask may be substituted for the simple tube here illustrated.

I firmly believe that the frequent estimation of ammonia by this method will give indispensable information to the diagnostician, without which his ideas of a given case will be correspondingly less definite, and his efforts in the line of treatment so much the more confined.

The important points of interest about the instrument are:

(1) Great rapidity whereby the estimation can be made.

(2) Simplicity and freedom from the need of any other apparatus whatever.

(3) Diminished original expense and cost of each test.

(4) Portability and the convenience of being able to perform accurate work anywhere, and without previous laboratory experience.

72 MADISON STREET.

The Use of Strophanthin in Pediatrics.—U. Franchetti has made use of strophantin in acute and chronic diseases of children for its effect on the heart and circulation. Contrary to the experiences of others that have been published, the author believes that this is an unsafe remedy in heart failure. It causes a marked arrhythmia and irregularity of the pulse. Used either endovenously or subcutaneously it has little beneficial effect in infants in asthenia and diphtheritic intoxication. In chronic heart diseases the author has little experience. The small doses used by the author, although they produced little beneficial effect, manifested toxic symptoms of importance.—*Rivista di Clinica Pediatrica.*

The Presence of Sudanophile Leococytes in Diphtheritic Infection.—Luigi Benini describes the results of blood examination in diphtheria. There is an increase of leucocytosis which intensifies with the severity of the infection. The use of antitoxin produces hypoleucocytosis after a half hour from the injection, followed by hyperleucocytosis lasting for twenty-four hours. The leucocytes contain granules that are named sudanophile, which indicate an intoxicating agent circulating in the blood and having a specific action on the blood. The author has made a study of these sudanophile granulations in the blood of patients at the Pediatric Clinic at Florence. There were ten cases of severe and twenty-nine of less severe diphtheria, and nineteen cases of laryngitis. Experiments were also made in animals. The author concludes that in diphtheria there are degenerative changes determined by the toxins of the disease, and these granulations are found in even the mononucleated leucocytes. No pus corpuscles are found. These sudanophile granules are more frequent in simple angina than in the croup cases. They are greater in number in severer cases and are an indication of the severity of the disease. They diminish on the third day of treatment and disappear as convalescence is established. They are not directly influenced by injections of antitoxin. In febrile complications they reappear, but are not found in postdiphtheritic paralysis. They are determined by the toxic action of the diphtheria toxin on the leucocytes of the blood.—*Rivista di Clinica Pediatrica.*

Radium and X-Rays in Gynecology.—Foveau de Courmelles has published his results in radiotherapy of fibromata and artificial menopause, showing the deep penetration of the *x*-rays. He uses aluminum shields and small doses, and the actual penetration of the rays thus used through the abdominal walls is no longer questioned. This is one of the best means of producing abortion when that becomes necessary on account of the mother's state of health. It is due to the action of the *x*-rays on the ovary and the thyroid body. This method has been used in a young tuberculous girl, at the third month of pregnancy, with success, in whom incoercible vomiting threatened life. After twenty-five applications of *x*-rays in series of four days over the ovaries, each lasting five or six minutes, the fifth day the rays being applied over the thyroid, the fetus and placenta were expelled normally. It is also useful for the treatment of uterine hemorrhage. The action of the rays on growths of the skin is well known. It has been found useful in relieving pain in blenorrhagic rheumatism. As a paint combined with inert substances radium has been used to obtain continuous action in treatment of nevi, angiomata, chancroids, eczema, and lupus. Used in this way, severe burns have been produced. For the stomach, urethra and uterus tubes are still used without danger. The *x*-rays have the effect on the mammary glands of drying up the secretion, preventing the development and causing regression of partly developed osein.—*Gazette de Gynécologie.*

Osteogenic Congenital Exostoses and Tuberculous Dystrophies.—L. Lortat-Jacob and G. Sabareanu give eight personal observations of osteogenic exostoses and sum up others found in medical literature. The authors believe that active tuberculosis in the father at the time of conception is an important factor in the production of exostoses in the infant, and in the absence of other determining causes this is found to be a frequent cause of dystrophies. Landouzy formulated two methods of transmission of the bacillus of tuberculosis: by the mother or father directly, and by the transmission of a diathesis only. The authors have found three cases of undoubted heredity of tuberculosis from the father. There may be found osteitic lesions of classic phlegmasic type or multiple hypertrophic lesions of the epephyses with rarefaction of the bone coexisting with tuberculosis in the same subject. They conclude that hereditary tuberculosis plays an important rôle in the production of congenital osteogenetic exostoses. Very little research in this direction has meen made. In these cases it is necessary to consider pulmonary tuberculosis, and all other more obscure forms of tuberculosis. Radioscopic examination of the patients is of great value in differentiating exostoses from other sources.—*Revue de Médecine.*

New York, August 28, 1909.

THE ETIOLOGY OF INFANTILE PYLORIC STENOSIS.

DURING the few years since the so-called congenital pyloric stenosis was first described, there has been much discussion as to the underlying cause of this serious and often fatal disease of early infancy, the differences of opinion being shown by the various names under which the condition has been reported, namely, congenital stenosis, congenital hypertrophy, and pylorospasm. Postmortem examination proves that there is an actual hypertrophy of the pyloric muscle and a stenosis of the pyloric orifice, while during life the *tactus eruditus* demonstrates the pyloric spasm. In a well-marked case all three factors are present at the same time, and the point of disagreement is as to which of them is primary, and the reason for its occurrence.

The advocates of the theory of congenital stenosis point to the marked lesions seen at autopsy, to the great hypertrophy of the pyloric ring, and to the true narrowing of the pyloric orifice. These, they claim, are anatomical changes much too great to have occurred during the short period between the child's birth and the onset of the symptoms. To their argument they add the fact that, on one occasion at least, the condition is said to have been demonstrated in a still-born child. On the other hand, the advocates of the pylorospasm theory emphasize the fact that the infant is born healthy, and remains so for several weeks, a condition incompatible with a marked anatomical stenosis. They further show the great rapidity with which muscular hypertrophy may occur at this early age, as is demonstrated by the tremendous thickening of the walls of the colon appearing in a very few days in cases of stricture of the rectum. They, therefore, believe that the primary disturbance is a spasmodic hyperactivity of the musculature of the pylorus, this activity leading to a physiological hypertrophy and a consequent stenosis.

Many reasons have been suggested for this abnormally active spasm of the pylorus. The theory which seems to be the most rational is that it is secondary to an abnormal gastric secretion. In 1900, Knopfelmacher reported two cases in which there was a high grade of hyperacidity, a finding which has been confirmed by observers in both England and America. More recently, Engel of Düsseldorf has had an opportunity to make a careful study of two cases, which he has reported in the *Deutsche medizinische Wochenschrift* for July 22, 1909. Both were typical examples of the condition. In the first case, though a jejunal fistula was made, through which the infant was fed, the vomiting continued and large amounts of gastric juice were expelled, enough to indicate a decided hypersecretion of the gastric glands. The author states that there was no hyperacidity, but his figures show that the hydrochloric acid content of the gastric juice, while not above that of the normal adult, was many times higher than that of the healthy infant, and that the child had in reality both a hypersecretion and a hyperchlorhydria. The second child was kept for some time on rectal feeding, during which a similar hypersecretion of a highly acid gastric juice was observed.

The quantity of hydrochloric acid in the stomach of the healthy new-born child is extremely small, the infant's gastric juice showing only about one-tenth the acid concentration that is found in the adult. It has been shown that one of the most powerful stimulants of pyloric contraction is the presence of acid in the duodenum. From these two facts and his own findings Engel draws the logical conclusion that in these cases of pylorospasm the primary condition is an increase in the amount of gastric juice, due, not only to hypersecretion at the time of feeding, but to a continual activity of the gastric glands, even when the stomach is empty of food, this highly acid fluid constantly overflowing into the duodenum and stimulating the pylorus to an excessive activity, with a resultant muscular hypertrophy and stenosis. For the underlying cause of the hypersecretion he says that, in his two cases at least, there was a strong neurotic family history, and he believes that he had to deal with a true inherited gastric neurosis.

This theory that the pyloric hypertrophy and stenosis are secondary to a spasm of the pyloric ring due to an inherited neurotic hyperacidity is thus based upon actual clinical observation and proved physiological facts, and is worthy of consideration, especially as it points out a possible method of treatment in a disease from which the mortality is now far too large. This is particularly true, as the theory agrees thoroughly with the favorable results reported by certain observers from the use of large doses of the alkalis in this disease. If, however, one waits until the condition is far advanced and the hypertrophy sufficient to produce true anatomical stenosis, the chance of recovery will be poor at the best. The especial value, then, of Engel's paper seems to be to teach that the hyperacidity antedates the pylorospasm. As it has been shown recently that the examination of the gastric contents of the infant is a simple matter and can be carried out as a clinical procedure, it is possible that an early use of the stomach tube in cases of the vomiting in young infants may be of especial value in this disease. It holds out some hope, at least, for the diagnosis of these cases of hyperacidity at a time when appropriate treatment, by overcoming the hypersecretion or neutralizing the hyperacidity, may relieve the pylorospasm and so prevent the pyloric hypertrophy and stenosis.

THE OUTLOOK ON TUBERCULOSIS.

Consumption in all its forms still holds the field as the most important, and, on the whole, most deadly disease. Modern methods of treatment have decreased its prevalence and perhaps diminished its virulence, but its extinction is yet far off.

At a recent meeting of the British Medical Association, Dr. R. W. Philip, of Edinburgh, delivered the address in medicine, taking as his subject the outlook on tuberculosis. He dwells on the fact that it seems in the light of modern observation that tuberculosis is commonly contracted in childhood, and if this conclusion be correct the problem to be faced is of a totally different complexion and proportions from that which was previously conceived. The point is how to prevent tuberculosis from attacking young children. Dr. Philip's views are not quite in accordance with those generally held. He thinks it is by no means proved that bacillus-containing milk is the most fruitful cause of infection in childhood, but is strongly of opinion that everything appears to point conclusively to the relatively airless conditions of home and school life as chief etiological factors. There are homes, indeed, which are veritable nests of tuberculosis, and, according to the speaker, tuberculosis is not only to be credited with a much greater proportion of mortality in childhood than is usually conceived, but is largely responsible for the aggravated manifestations of otherwise simple ailments.

As for the occurrence of tuberculosis in the community generally, Dr. Philip deems that it is far more prevalent than is commonly believed, and he concludes that the mortality within a district may safely be multiplied by ten to express the number of cases of pulmonary tuberculosis worthy of medical surveillance. The entire number of persons who give a positive reaction to tuberculin is very large, and testifies to the tremendous grip which tuberculosis has obtained on the race and its immense ramifications throughout the social organization.

Concerted action is therefore necessary to take measures in order that dwellings and schools, as well as workshops, offices, etc., shall be under proper sanitary control, and especially is it needful that housing in its widest sense shall be most carefully supervised. Treatment of individual patients is not enough, if the disease is to be stamped out, but they must be searched for in their hiding places and the disease be tracked to its breeding grounds.

Of aërotherapy in its relation to tuberculosis, of course, Dr. Philip speaks in the highest terms. The brilliant results achieved by the open-air treatment have been so patent that it is unnecessary to dwell on the subject so far as treatment is concerned. With regard to prevention, however, there is no doubt that aërotherapy is less employed than in treatment, although what is capable of effecting the cure of definite tuberculosis is, *a fortiori*, capable of preventing its appearance. If the principles of aërotherapy were to be carried out thoroughly in all homes and in places where persons congregate, then tuberculosis would manifest in a comparatively short time a remarkable decrease. In the treatment of the great majority of diseases, and of tuberculosis in particular, prevention is the goal at which to aim. When the conditions of the mode of life of the mass of town dwellers are altered for the better, then and not till then will there be any chance of tuberculosis being abolished.

Dr. Philip is not so enthusiastic regarding the value of vaccine therapy in tuberculosis as are some. He sums up the limitations of tuberculin from the physiological side as follows: "So long as the local process is the main feature—that is, so long as systemic disturbance remains relatively slight—we may anticipate benefit from treatment by tuberculin. On the other hand, with advancing intoxication there comes a time when the introduction of tuberculin ceases to have value, or when the introduction of tuberculin may do positive harm. Where the system is already soaked with tuberculous toxins the addition of tuberculin will probably make matters worse. The possibility of activation of leucocytes and bacteriotropic elements no longer exists. The limits of activation have been passed."

Concerning the larger prospect of tuberculosis, Dr. Philip is very optimistic—many will think unduly optimistic. He believes that everything points to its early and final disappearance, and states that this should not be impossible of achievement within a generation or two among the nations which regard public health as an integral part of civilization. The main object in the crusade against tuberculosis is to awaken the public conscience and to educate the community at large with respect to the intelligent methods of preventing the disease. The proper rôle of the physician is that of the educator.

THE DEFECTIVE CHILD.

The defective school child has recently been made the subject of an important investigation in Germany. In striking contrast to the tardiness with which New York City has awakened to the necessity of establishing special schools for defective children, Germany had already set a good example, for in 1905 there were 230 such schools in 150 German provinces, registering 15,000 children. That this enormous material furnished an enviable opportunity for studying the origin and antecedents of the various forms of degeneration encountered early in life was fully emphasized seven years ago by the illustrious psychiatrist Kraeplin, and has recently led to some important researches conducted by Eugene Schlesinger (*Archiv f. Kinderheilkunde*, Vol. 16, No. 1).

The analysis by this careful investigator of the past history and antecedents of 138 defective school children showed that in 27 there was no predisposing event that could be considered sufficiently important to have causative relationship to the present defective conditon. In 24 per cent. of the remainder there were unmistakable evidences of degeneration in the brothers and sisters. In 17 per cent. of the cases truancy may have accounted for the mental backwardness, while in 13 per cent. this was attributed to conditions associated with abject poverty in the home. In most of these cases alcoholism in the parents was a coincident circumstance, but its causative rôle was distinctly apparent in only

2 per cent. of the cases. Ten per cent. of the cases revealed a neuropathic inheritance, but many of these cases could be explained on the basis of severe antecedent illness in the child, particularly nervous diseases, such as epilepsy, cerebral paralysis, and cerebral syphilis, and also to tuberculosis, diseases of the eye, or to the severe disorders of infancy. In 6 per cent. the defective condition was closely linked with defects in speech, in 5 per cent. with psychopathic deficiencies, while only rarely was deafness found to be a cause. In contrast to these etiological factors, only seldom did birth traumatisms, injuries to the head during early childhood, and atrophy of the thyroid, play any rôle, while the fact that hypertrophied tonsils were so widely prevalent excluded these as important factors in the production of the defective condition. In only 3 per cent. of the cases was the condition purely hereditary, and in 8 per cent. purely acquired, while in the remainder hereditary and acquired influences were both operative. In these, however, the acquired factors predominated.

The above figures are pregnant with significance, for they emphasize the eminent importance of environment, and the urgent need of early prophylaxis in diminishing the ranks of the school defectives.

Loosing the Insane Criminal.

The recent, fortunately unsuccessful, attempt of Thaw to escape by the aid of the courts from the hospital where he is confined, gives added interest to a paper read last January before the New York State Bar Association by Dr. Robert B. Lamb, Medical Superintendent of the Matteawan State Hospital. In this paper the writer reviews the laws bearing upon the commitment and discharge of the criminal insane and proposes certain changes suggested by the actual operation of these laws. To anyone giving a second thought to the subject, it must be evident that a jury of laymen should not be allowed to decide regarding the mental condition of any person with a view either to his commitment to an asylum for the insane or to his discharge therefrom. As to the practical results of such a procedure, it is stated that some years ago fourteen persons were committed to one small hospital by juries in a single year, and every one of them was found to be sane and had to be discharged. Regarding discharges from Matteawan, Dr. Lamb refers to his notes of thirty-four cases in which the court ordered the discharge of the person from the hospital as being sane. Of this number fourteen found their way back to either prison or asylum; eight, after their release, showed signs of mental disturbance, and were troublesome to their families; three, unable to earn their own livelihood, were cared for by their relatives; six disappeared from view; two committed suicide, and a single one, when last heard of, was partially self-sustaining. It is especially noteworthy in this connection, the author says, that "in all cases referred to which have been submitted to juries for verdict, the finding has been uniformly in favor of the lunatic, without regard to his previous history. It is equally noteworthy that when a judge has investigated the case his finding has been in favor of the hospital." He concludes from the study of this record, and we think few will be found to disagree with him, that there should be some modification of the present law, whereby lunatics accused of serious crimes against the person, and especially those committing murder, should be dealt with by a tribunal having fixed continuous responsibility.

Radium Treatment of Filariasis.

Radium is emerging from its position as a more or less unknown quantity in the treatment of disease, and will soon perhaps take a definite place in the armamentarium of the practising physician. For some time it has been employed with generally fairly satisfactory results for certain superficial forms of carcinoma, and by Abbe for deeper growths and for sarcoma as well. In England it has been used with some success in the treatment of lupus, and more recently its efficacy was demonstrated as an application for reducing the number of vessels in nevi, so that the remedy is now being somewhat largely utilized for the extirpation of birthmarks on conspicuous parts of the body. That radium does affect the tissues to some extent, albeit its action may be unequal, is the opinion of the majority of physicians who have tested it, and in this connection a note by Dr. A. A. Warden of Paris on the treatment by radium of lymphatic obstruction, cervical, submaxillary, and axillary, in a patient suffering from filaria nocturna will be of interest. In the case under notice removal of the axillary mass by operative interference had been attempted and abandoned on account of prolonged syncope under chloroform, and further operation had been negatived by a London consultant. Filaria nocturna embryos were found in the blood when the patient returned from England, and treatment by means of radium was begun. The enlarged glands were exposed to the action of radium, but only the more penetrating rays were permitted to reach the body, the other rays being excluded by the agency of screens of lead and of other materials. No rays, indeed, but the gamma and the ultra-penetrating beta, were employed, and thus injury to the skin was avoided. The treatment entailed no discomfort or pain to the patient, and under its influence the several glandular masses rapidly diminished in size, and as the temperature also declined, it is probable that the radium had an influence on the filaria. As it was found that the tumors continued to diminish in size when treatment was suspended for ten days, and as the patient was anxious to return to England, it was decided to postpone further action till later if necessary. There is undoubtedly much yet to learn concerning the employment of radium as a remedial and curative agency, but our knowledge is increasing daily, and it is becoming more and more evident that this element will play in the future an important rôle in the field of medicine.

Psychosis Following Lightning Stroke.

The opportunity to study after-effects in persons who have been struck by lightning is not a very common experience. In more than half of the cases the result of the stroke is instant death, and in those cases that recover the amount of the current passing through the body has usually been so slight that, except for temporary shock and possibly a transient neurosis, the after-effects amount to little or nothing. Occasionally, however, the

destructive action of the bolt, though not great enough to kill, may be sufficient to produce definite anatomical and functional lesions. Blindness has been reported in a few cases, and deafness in others, while paralysis of single members, or even complete hemiplegias, have been seen. The occurrence of psychoses following lightning stroke is, however, distinctly rare, so much so that in most of the text books on psychiatry practically nothing is said about it as an etiological factor in mental diseases. In view of this a case reported by Becker in the *Münchener medizinische Wochenschrift* for July 27, 1909, is of interest. A strong, healthy woman was struck by lightning while at work, and fell to the ground unconscious, a state which lasted for some time, and was associated with a complete left-sided hemiplegia. After the return of consciousness, while the paralysis improved gradually, definite mental symptoms appeared, and a progressive psychic degeneration was evident. The patient developed fixed ideas, delusions, and perversions, especially of a sexual character. She was obscene in her language, and filthy in her habits. Her memory was poor, and grew steadily worse. The complete picture was that of progressive senile dementia. After many months, trophic ulcerations appeared on the right leg, which, though they showed variation in their extent and occasionally closed over, soon broke down again, and had but little tendency to heal. A point to which Becker draws attention is that, whereas the paralysis was of the left side, the trophic disturbances were in the right leg. From this he concludes that the former was due to cerebral injury, but the latter were the result of the local action of the fulguration upon the vasomotor nerves of the leg.

News of the Week.

Army Medical Corps Examinations.—The Surgeon General of the Army announces that the War Department has appointed a permanent board to sit at Washington, D. C., for the preliminary examination of applicants for appointment in the Medical Corps of the Army, in addition to the usual preliminary examination boards that are assembled at various army posts throughout the United States from time to time. The board at Washington will probably hold its first session about September 7, 1909, and on such other dates thereafter as may be designated by the Surgeon General. Physicians who are successful in the examinations by the Washington board will be given employment at Army posts, as their services are needed, as First Lieutenants, Medical Reserve Corps—salary $2,000 per annum—until the next session of the Army Medical School, when they will be ordered to attend the School as "student candidates." Full information concerning the examination can be procured upon application to the Surgeon General, U. S. Army, Washington, D. C. The essential requirements are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice. The examination in subjects of general education (mathematics, geography, history, general literature, and Latin) may be omitted in the cases of applicants holding diplomas from reputable literary or scientific colleges, normal schools or high schools, or graduates of medical schools which require an entrance examination satisfactory to the faculty of the Army Medical School. Applications for permission to take the examination may be filed with the War Department at any time. Unless the statement is made that the candidate desires to appear before the Washington board at or about a certain time, arrangements will be made to have him examined before the next board assembled in his vicinity.

The Holmes Centenary.—The Medical Society of the County of New York has appointed a committee to arrange for the celebration of the one hundredth birthday of Oliver Wendell Holmes. Properly speaking the celebration should be held on August 29, but inasmuch as so many physicians are out of the city at this time, October 9 has been set instead. The speakers will be Dr. M. H. Richardson of the Harvard Medical School who will give some "Personal Reminiscences of Oliver Wendell Holmes;" Dr. E. O. Otis of Tufts Medical School who will recite "Dr. Holmes' Achievements as a Physician," and Dr. William Hanna Thomson of New York City who will choose some topic dealing with Holmes' versatility. Five members of the County Society have the arrangements in hand: Dr. Irving Wilson Voorhees, chairman; Dr. S. Adolphus Knopf; Dr. David Bovaird, Jr.; Dr. H. Seymour Houghton, and Dr. John Leshure. Hon. Oliver Wendell Holmes, Judge of the U. S. Supreme Court, has been invited to be present.

Medical Service in the Hudson-Fulton Celebration.—As noted in a previous issue, extensive preparations are being made by the National Volunteer Emergency Service to establish a number of field hospitals and first-aid stations on the Hudson River front, extending from the Battery to Spuyten Duyvil, and along the line of march during the Hudson-Fulton Celebration, which will take place from September 25 to October 9. The work is under the direction of a committee composed of Drs. James Evelyn Pilcher, F. Elbert Davis, George Morgan Muren, John C. MacEvitt, and D. R. Lucas. Physicians, pharmacists, nurses (male and female), and former hospital stewards wishing to volunteer their services for assignment may address: The Adjutant General, National Volunteer Emergency Service, 130 West Fifty-sixth street, New York City.

An Association for Clinical Research.—A call has been issued for a meeting of physicians and surgeons interested in Scientific Clinical Research to be held Wednesday, October 27, 1909, at John Ware Hall, Boston Medical Library, No. 8 Fenway, Boston, Mass. The meeting will come to order at 10 A.M., and carry its sessions through Wednesday, and, if necessary, through Thursday and Friday. The objects of the meeting are: (1) To establish an American Association of Clinical Research; (2) to establish clinical research on an incontrovertible scientific basis in hospitals; and (3) to institute a journal in which the work of members of the American Association and of others doing clinical research work in a scientific manner shall be published. The call states that the American Association of Clinical Research is not intended to disturb the present medical affiliations of its members, but is to take cognizance of the fact that the clinic requires facts and conclusive methods, and upon

these fundamental requirements, the structure and the work of the Association are to be built. "It is of the utmost scientific importance to establish conclusively all that is at present true in medicine and surgery, and only upon such proved knowledge, to base any further advancement. The clinic deals with clinical entities and not, like the laboratories, with parts as entities. Therefore, clinical research differs, and must differ, from experimental laboratory researches. Clinical research must consider clinical entities, and when considering parts, it must consider them only as parts and not as wholes. All that subserves the object of obtaining and investigating clinical facts and principles belongs to clinical research and the laboratory is a part of the means of clinical research, but only a part. . . . Conjoined critical observation and experiment, at the bedside and in the laboratory, as may be required, furnish simultaneous identical experiences, the proof proceeding on the principle that a whole can be proved only by the whole and not by dislocated parts." Communications may be addressed to James Krauss, M.D., Chairman Committee American Association for Clinical Research, 419 Boylston street, Boston, Mass.

Mosquitos in New Jersey.—Prof. John B. Smith, head of the New Jersey Entomological Experiment Station, has recently made an investigation of the counties in which most of the work of exterminating mosquitos has been carried out during the past six years, and reports that in the counties of Essex, Union, Middlesex, Monmouth, and Ocean the salt water mosquitos have been practically eliminated. The many miles of ditches which have been constructed to drain the salt marshes are open and unobstructed, and the land between, formerly swamp, is dry and firm, producing good crops of marsh hay. In all about 10,000 acres of meadow and salt marsh has been drained and reclaimed at an expense of $5 per acre.

Tuberculosis in Public School Children.—A report recently issued by the Association for Improving the Condition of the Poor states that of 728 children, 381 boys and 347 girls, at Sea Breeze, in West Coney Island, subjected to the tuberculin test, 205, or 28.1 per cent., showed a positive reaction. The investigation was undertaken at the suggestion of Superintendent Maxwell and of Dr. Brannan of the advisory board of the Sea Breeze Hospital, and was in a measure a preliminary step to determine the need of open-air schools in New York City.

Floating School for Tuberculous Children.—Kindergarten classes are being carried on, and later regular school will be opened, on the Brooklyn Floating Hospital for Tuberculosis. The hospital consists of the old ferryboat *Susquehanna,* which was obtained for the Brooklyn Tuberculous League by Miss Mary Harriman. It is supported by the Red Cross Society. The kindergarten is under the care of a graduate of the Kindergarten Department of the Pratt Institute. The hours of attendance are from 9 A.M. to 5 P.M.

Pure Water in Columbus.—The vital statistics of Columbus, Ohio, show a decided improvement in the city's health since the inauguration of a filtration plant for the city water. Last June there were 159 cases of typhoid. This year there were five cases up to the 20th of the month. Every month so far this year there has been a general decrease in the number of deaths. Last May there were 25 cases of scarlet fever and 10 in June. This year there has been none. Last year there were 3,114 cases of infectious and contagious diseases reported during the year, but if the present ratio keeps up there will be less than 1,000 this year. A movement is now under way to investigate the well water supply of the city. Every well in the city is to be examined and the results published so as to put the users on their guard. Recent examinations of the city water by the city bacteriologist showed from four to eighteen bacteria per cubic centimeter, while various samples of well water varied from 300,000 to 800,000 per cubic centimeter.

State of Chicago's Health.—According to the Bulletin of the Health Department, August 7, no summer in the history of Chicago has been healthier than the present one. The general death rate, the infant mortality rate, the death rates from the diarrheal diseases and from typhoid fever are the lowest on record. The mortality record of the week just closed is a continuation of this most gratifying condition. The general death rate of the week was 12.33 per 1,000 of population on a per annum basis, this being 15.5 per cent. lower than the usual rate of this season. The total deaths of the last week, 526, were 131 fewer than the corresponding week of last year; the child mortality under five years of age was 108 lower; the diarrheal deaths were 72 fewer, and there were 5 fewer deaths from typhoid fever.

Infantile Paralysis in St. Paul.—What appears to be a severe epidemic of anterior poliomyelitis is at present prevalent in St. Paul, Minn. Up to August 7, twenty-two cases had been reported in the city. After that the epidemic increased in severity, as on August 10 and 11 twenty new cases appeared and two deaths were reported. The Minnesota State Board of Health is taking active steps in the investigation of the epidemic.

Scarlet Fever in Milwaukee.—An epidemic of scarlet fever has been prevalent in Milwaukee this year, as is shown by a record of eighty-one deaths from the disease during the first six months of 1909 as compared to eight deaths for the same period in 1908.

New Supply of Radium.—According to reports from California a new immense supply of pitchblend, said to be enough to supply the world with radium for all time, has been discovered on the McCloud River, north of Kennetta, Cal.

The Late Dr. George M. Beard.—Miss Grace Alden Beard, 675 Flatbush avenue, Brooklyn, N. Y., would be grateful if any readers of the MEDICAL RECORD having in their possession any books, pamphlets, manuscripts, or letters, written by her father, the late Dr. George Miller Beard, would communicate with her regarding the same.

Dr. Robert Henry Wolcott, Professor of Anatomy in the University of Nebraska, has recently been appointed acting dean of the medical college of that institution.

The Universities of Tennessee and Nashville have recently formed a union of their medical departments. The combined university has adopted the entrance requirements, curriculum, and graduation requirements suggested by the association of American Medical Colleges. The building formerly used by the University of Tennessee is being converted into a hospital. Plans have been prepared for a new hospital on the grounds of the

University of Nashville. These two hospitals when completed will be used for teaching purposes.

The Sullivan County (N. H.) Medical Society was reorganized at a meeting held at Claremont, August 11, and the following officers elected: *President*, Dr. E. C. Fisher of Sunapee; *Vice-President*, Dr. Fred P. Claggett of Newport; *Secretary*, Dr. Emery M. Fitch of Claremont; *Treasurer*, Dr. D. M. Currier of Newport; *Board of Directors*, Dr. A. S. Marden of Newport, Dr. O. C. Young of Charlestown, and Dr. H. C. Sanders of Claremont.

Obituary Notes.—Dr. Casper K. La Huis of Zeeland, Mich., and formerly of Kalamazoo, died at his home, August 12, 1909, aged 40 years. He was a graduate of the University of Michigan in 1896 and was a member of the Kalamazoo County and Michigan State Medical Societies.

Dr. George Moran of Detroit, Mich., died at the Harper Hospital in that city, August 12, 1909, from an attack of ptomaine poisoning, aged 41 years. Dr. Moran was a graduate of the Iowa State University and received his medical degree from the University of Michigan in 1892. He was chief of the medical staff of the St. Vincent's Orphan Asylum, and a member of the Wayne County Medical Society, the Michigan State Medical Association, and the American Medical Association.

Dr. Daniel L. Sweeney of Newark, N. J., died at his home on August 20, 1909, aged 61 years. He was a graduate of the College of Physicians and Surgeons in New York, in 1882, and was a member of the Essex County Medical Society and the Medical Society of New Jersey.

Dr. Robert Walker Robinson of Auburn, N. Y., died at Northport, Me., on August 21, 1909, aged 49 years. Dr. Robinson was a graduate of the Long Island College Hospital Medical School in 1884, a member of the Cayuga County Medical Society, the New York State Medical Association, and the American Medical Association, and visiting physician to the City Hospital of Auburn.

Correspondence.

THE FOMITES THEORY.

To the Editor of the Medical Record:

Sir:—I have read with interest your editorial comment on Dr. A. H. Doty's article on "The Means by Which Infectious Diseases Are Transmitted." I have in mind the conservative expressions made years ago, when Lister first taught that the presence of pus in a surgical wound was a disgrace to the operator, and generally due to his negligence, and again I remember the tenacity with which many held to the idea that heredity was the cause of tuberculosis; and, yet again, the tearing of heart strings when the mephitic environment theory of the origin of malaria was attacked. A theory of reputable parentage becomes after a time well-rooted, and by the aid of apparently well-established facts becomes a part of our knowledge (?), but sooner or later careful observation, practical and unfeeling, sweeps away the cherished belief, and it is buried, after a long "wake," and is soon practically forgotten, and its memory serves only to aid in the sepulture of another theoretical delight.

After some twenty years of intimate observation of infectious disease in the service of the Department of Health of this city, I find myself in full accord with the position of Dr. Doty in his present antagonism to the fomites theory of the transmission of infectious disease. Is it not a suggestive fact that half a continent must generally separate the initial disease and the "woolly lamb" host, in view of the fact that apparently similar claims of the origin of disease, in our local experience, have proved to be fallacious? Contrast the uncertainties of these almost foreign instances with the absolute facts connected with the service of health officials who have been exposed for hours in the pesthholes of this city in times of epidemics described by Dr. Doty, and have not known of any transmission by clothing worn during official service. If this were not a generally accepted fact, based on the experience of years, do you imagine that service in the Department of Health would still be eagerly sought by physicians?

I do not believe that the handlers of filthy lucre are any more exposed to infectious disease than men of other occupations, for the reason that in my experience few of those who are victims of infectious diseases are found to have any financial responsibilities, and the possession of paper money to most of them would give a shock almost equal to that occasioned by this well-timed attack on a pet theory of sanitary science.

In the light of experience, I am of the opinion that the danger of transmission of scarlet fever, measles, and diphtheria in the schoolroom is not in the clothing worn by well children from infected families, but rather in the fact that initial symptoms of these diseases are often overlooked, and that the children supposedly well attend school when first attacked, and thus transmit disease. With reference to smallpox, it is well to remember that a single vaccination in infancy is not now considered a complete protection (hence the frequent vaccinations performed in lodging houses and eleemosynary institutions), and that a large number of persons are in error when they believe they are immune by reason of infantile inoculation. I believe that the author of the paper under discussion is upon safe ground, and that a positive service to sanitary science will be the outcome of this attack on a time-honored, but perfunctory and useless theory.

Charles S. Benedict, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ECHOES FROM BELFAST—HOSPITAL SUNDAY FUND, VIVISECTION, AND SIR W. CHURCH—SMALL SPECIAL HOSPITALS—ROYAL COLLEGE OF PHYSICIANS.

London, August 6, 1909.

Visitors to Belfast began to return on Friday, when the sections were finished, though many remained over Saturday to take a share in the many excursions provided. In fact, all along the picnic element seems to have overshadowed the scientific, which is perhaps to be expected when this is divided into fifteen sections, and few could be interested beyond their own. Several of these are described to me as successful, some of them very much so.

The abounding hospitality shown seems to have stamped the meeting as almost unprecedented. Much of the success of the social functions was evidently due to the visit of the Viceroy and Lady Aberdeen, who, as I have told you, received full recognition of her splendid campaign against tuberculosis.

Sir William and Lady Whitla also displayed a lavish hospitality, which, highly appreciated by all, set some thinking that the example might possibly deter a future presidency being accepted by some one who could scarcely afford to follow. Sir William is a J. P. and has held all positions available for a physician in the city of his long residence. He defrayed the cost of building the Institute of the Ulster Medical Society, which was opened about seven years ago. He has also taken an active part in matters rather philanthropic than strictly medical. He was knighted in 1902. You will perhaps know him best for his "Materia Medica," which has passed through several editions and been translated into Chinese. But he has contributed freely to the journals and published other works.

I now pass on to add a few disjointed remarks I have gathered respecting the meeting. Those interested in sanitary works had the opportunity of studying on the spot, with the assistance of Councilor McCullagh, the sewage system which has been a sore trouble to Belfast for the last ten years, but which it is hoped has now been, or soon will be, completely overcome. The growth of the *ulva latissima* is so rapid in sewage effluents that tons of it were continually being removed from the shore, where it putrified and gave off an odor of sulphuretted hydrogen. Professor Letts found that not only ammonia, but other nitrogen compounds, were an excellent food for the ulva. After many experiments, he found that a double decomposition might be obtained by mixing two effluents, one highly nitrated, the other from the septic tank. The

result is pronounced practicable by several professors who spoke in the hygiene section and it is hoped that Belfast will soon become a model.

In the Psychological Section Dr. Dawson of Dublin had a paper criticising the report of the Royal Commission on the Care of the Feeble-minded. He found it difficult to see what good would be done by the oversight and certification recommended. To change the terms "lunatic" or "asylum" could not be of more than temporary influence. It was useless to talk of a distinction between persons of "unsound mind" and those "mentally infirm." He seemed to think classification of little use.

Dr. Maguire of Belfast urged the necessity of setting apart wards in general hospitals for border-line cases and said more institutions were needed in Ireland. Some of our London men hold similar opinions.

The tour of the Royal Victoria Hospital was a notable function, embracing a reception by the chairman, who provided at his own expense the entertainment and refreshment for 500 invited doctors and 1,000 members of the public, in order that they might see the way in which the hospital is conducted and the comfort of the patients cared for. The chairman, Mr. James Davidson, with his daughters, received the guests. The medical visitors declare the hospital one of the best equipped in the United Kingdom. The operating theater and electrical departments are specially well spoken of. In the latter *x*-ray apparatus is installed and everything, I am told, is up to date.

The noble City Hall, of which the citizens of Belfast are very proud, was the scene of a reception by the Lord Mayor and Lady Mayoress, described by one present as delightful and showing that Ireland's proverbial hospitality has "not been exaggerated and they do know how to do things." The Lord Lieutenant and Lady Aberdeen were present and when they left, after supper, dancing began. One person says there must have been nearly 3,000 guests in the vast building.

The Museum of Sanitary Science, Queen's University, was visited by many. It was established in January, 1899, at the cost of Dr. Henry O'Neill, J. P., and his wife, who have continued to defray the expenses of its maintenance.

The Pathological Museum offered another sight with its array of microscopes and preparations. Specimens of parasites were among the sections and motile bacilli were also exhibited.

The rulers of the Association have at this meeting experienced a shock at the open expression of discontent with their management, and more particularly with the *Journal*. As to this, there has for years been a number of advocates of change, or, as they would say, reform. The dissatisfaction took the form of more than one proposal in the representative meeting. Some wanted the paper to be supplied at a separate charge instead of being included in the subscription, which could thus be lowered. Others wanted the supplement to be restricted to members and not sold, as they feared "their enemies" might, through it, become acquainted with their "private affairs." So insistent were some you would think there was some dreadful secret about their doings. Another objection of a more general kind related to the advertisement department. After some years of talk outside, a resolution was actually brought in condemning the insertion of certain advertisements, and adding that the "present condition of the advertisement pages is not creditable." The resolution was freely discussed and various modifications considered, but the upshot of it was that the matter be referred to the Council.

In rather a large circle the *Journal* is spoken of as the "great unread." It is not for me to decide whether this is to imply excessive bulk or heavy reading, or both, but I may tell you a story related to me by a doctor. He says he lately went to the sale of a deceased fellow practitioner, who had been a long-standing friend, and in the top room, awaiting the auctioneer, he saw the numbers of the *Journal* for twenty years, not one of which had had the postal wrapper removed.

The annual meeting of the Council of the Hospital Sunday Fund was held on the 28th ult., when a step was taken which is causing severe criticism and indeed general condemnation in the profession. In the distribution proposed a sum of £48 15s. was recommended to be given to the Antivivisection Hospital, which, of course subsists on contributions of the fanatics for the sake of libelling the physiologists.

Sir William Church moved the adoption of the report. The Council, he said, did not approve the methods employed at that institution, but there was evidence from a number of the clergy in the district that the poor were benefited by it. He therefore proposed to double the sum recommended. This from Sir William Church, who has heretofore been regarded as a representative physician. The proposal was seconded by a lord and carried against the protest of Dr. Thomas Brown, who said the hospital was a slur on the profession and proposed no grant should be made to it. Strangely enough, no one seconded him. This is by no means the first time that the Sunday Fund has acted in a way to provoke medical criticism. In one case several years ago a deputation was, to my knowledge, positively insulted when it urged the claim of a really well-conducted small hospital. Now we see it pandering to the supporters of a little movement of hatred of science and common sense. I commend Sir William's conduct to the censors of the College of Physicians.

The establishment and carrying on of small special hospitals for which there is no need trespasses on the charitable funds of the nation. An example this week is an appeal in the Times for £35,000 for the Heart Hospital, an institution which ought never to have been established and which it would be a good thing to close. Its supporters want to remove it to a new site and ask for this £35,000 for that purpose. The house may be ill adapted for the twenty-six beds it is said to offer to sufferers from heart disease—patients readily admitted to all the large hospitals, all of which are in need of funds. Let the charitable give to them rather than to a small affair which has done nothing to entitle it to help.

Dr. Joseph A. Ormerod, M.A., M.D., Oxon. F.R.C.P., physician to St. Bartholomew's Hospital, has been appointed registrar of the Royal College of Physicians in succession to Dr. Liveing, retired.

Miss Ivy E. Woodward, M.D., Lond., has been admitted on examation to membership of the Royal College of Physicians, the first female to attain that diploma. She was a student at the Women's School and Royal Free Hospital and afterward pathologist and house physician there.

A cycle accident has caused the death of Dr. Arthur Foxwell, senior physician to the Queen's Hospital, Birmingham, and professor of therapeutics in the university. He was formerly editor of the Birmingham Medical Review and contributed articles to other journals.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

DIAGNOSIS OF HYDATID CYSTS OF THE LIVER—SPOROTRICHOSIS—EXTIRPATION OF THE SPERMATIC DUCTS IN GENITAL TUBERCULOSIS.

PARIS, July 31, 1909.

In a recent paper Chauffard shows that the diagnosis of hydatid cysts of the convexity of the liver has for a long time been difficult and uncertain. In cases of this kind the cyst develops in the direction of the least resistance, extending to the diaphragm, which is crowded upward along with the base of the lung. In the end it may fill one-half to two-thirds of the right thorax. The differential diagnosis from pleuritic effusions is very difficult to establish. Modern methods of diagnosis aid us in a marked way in this disease. If radiography shows the obscure zone limited above by a curved line convex above, and the examination of the blood shows a marked eosinophilia, and the examination for the deviation of the complement is positive, the diagnosis of hydatid cyst of the convexity of the liver is considered to be positive. But we must recognize that there are cases in which all the laboratory tests fail. To make the diagnosis more precise Chauffard demonstrates a physical sign, which, according to him, has great clinical value—it is the transthoracic wave. To obtain this sign we place the patient in the upright position, the left hand extended on the posterior wall of the thorax below the scapula. At the same time, with the index finger of the right hand light percussion is made in front over the fifth and sixth ribs and interspaces. There is felt a series of little wave-like vibrations, which give the sensation of transthoracic waves. This sign of the transthoracic wave is very special, for nothing analagous can be obtained in pleuritic effusions, small or large. Aside from the fact of fluid contained in the thorax not being encysted, the body of the lung crowded backward stops and breaks

the vibrations which might have been produced. To sum up, this sign of the transthoracic wave appears to be of a nature to render great service in the more precise diagnosis of intrathoracic collections which it is often difficult to differentiate.

At the recent meeting of the Medical Society of the Hospitals sporotrichosis was the subject of study. Sporotrichosis appears to be a disease peculiar to France, although Robert Stein has observed a typical case at Berne. It was that of a patient forty-five years of age, who presented multiple abscesses which developed without any pain during the few previous weeks, and without any general symptoms. His trade was that of a dishwasher in a hotel, where he manipulated for several hours a day in dirty water soiled by dishes and scraps of food. He burned his forearm and neglected the wound, which became transformed into an abscess; other similar abscesses formed on the limbs and on the trunk. The ulcerated masses became covered by a crust of a yellow color surrounded by a reddish violet inflammatory zone. The contents of two abscesses were cultivated on appropriate media and after eight days the culture showed a typical sporotrichosis. Pautrier and Lutembacher thought it might be possible to obtain in patients afflicted with sporotrichosis, by the introduction of the special products of sporotrichosis, a reaction analogous to that obtained in tuberculosis with tuberculin. The certain diagnosis of sporotrichosis rests to-day on the obtaining of cultures, to which it is almost always necessary to have recourse to confirm the clinical symptoms. Now these cultures require from seven to eight days to mature; sometimes they are even longer in growth and do not take on typical characteristics until the tenth to the twelfth day. It would be interesting to possess a diagnostic method at the same time more rapid and certain. These authors thought that these germs might not produce poisons analogous to those of Koch's bacillus, which give tuberculin its specific action in tuberculosis, and they began experiments starting out first with the spirotricum itself dead and sterilized, instead of with its products, and they acted as would a bacillus killed by its own endotoxines. Taking a portion of a young culture of sporotrichum, they diluted it with ten cubic centimeters of serum and sterilized it by boiling. They injected one cubic centimeter of this dilution into a patient attacked by sporotrichosis, and obtained a quick, painless reaction at the point of injection. It manifested itself by a redness of the skin with diffuse edema. In a control patient they injected the same amount of the same solution and obtained no reaction at all, general or local. Beurmann and Gougerot thought that they might be able to diagnosticate rapidly sporotrichosis by means of the intradermic reaction. After collecting portions of young cultures, they diluted them with serum and sterilized at 100°. They then injected this liquid into the thickness of the skin in the dose of one or two drops. The local reaction was marked, the general nil. In the positive cases there formed in the skin a red nodule with a rose violet areola, lost in a markedly edematous disk. The intradermic reaction seems, then, to assure the diagnosis of sporotrichosis in its earliest stages.

At the Society of Surgery Pauchet of Amiens read a paper on the "Extirpation of the Spermatic Ducts in Genital Tuberculosis." Cases of genital tuberculosis are frequent and the rational treatment of them seems to be surgically the total extirpation of the diseased tissues. Spontaneous cure of lesions of the seminal vesicles and prostate seems not to exist. The difficulty of the operation seems not to be a good reason for abstaining from it. Since we have performed perineal prostatectomy, access to the lower surface of the bladder and vesicles has become easy and the operation benign. The operative technique to be followed consists of three steps: The first inguinal, second scrotal, and third perineal. The inguinal portion consists of dividing the inguinal ring, reaching the deferent canal and separating the tissues about it; the dissection is pursued very deeply into the pelvis to the neighborhood of the bladder; section is carried out with the galvanocautery between two ligatures. The second step, the scrotal, consists of bringing the testicle into the inguinal incision; the epididymis is resected when it presents lesions. The third step, the perineal, consists of making a linear, transverse, bi-ischiatic incision; the rectum is pulled down, the prostate uncovered, and the seminal vesicle is seen and removed. Total extirpation of the spermatic ducts should enter into surgical practice as benign, easy, and often efficacious.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 12, 1909.

The Problem of Cancer Considered from the Standpoint of Immunity.—Independently of Schone, Frederick P. Gay tried about one year ago the effect of implanting tumors in animals from which the first tumor had been removed. Instead of waiting eight days, as did Schone, he reimplanted the tumor immediately after removing the first tumor, and found that whereas this second tumor failed to take in tumor animals up to the thirtieth day of growth, it took in them from that period on. This period of thirty days corresponds rather closely to the time during which no metastases are evident following inoculation of the tumor in most susceptible animals. In these susceptible animals which take the tumor in 100 per cent. of cases, metastases occur at a rather definite period following implantations of a uniform amount. This period is between thirty and forty days. He also found that if animals were given a second implantation of tumor up to the period of thirty or thirty-five days, without removal of the primary tumor, not only did the second tumor fail to take, but the first tumor actually disappeared. As a result of experiments he has found that in approximately 50 per cent. of the animals treated during the first three or four weeks of tumor growth, reimplantation of tumor will lead to a cure of the original tumor and a preventation of metastases. It would seem justifiable, as a working hypothesis, to regard the pre-metastatic period of a tumor as the period during which the animal shows reaction products to cancer tissue, and during which period the animal is also able successfully to combat a generalized infection of the cancer. In those cases in which spontaneous resorption of the tumor occurs, which are relatively frequent in animals, and have also been described in human beings, we may suppose that the resistance of the individual has succeeded in overcoming the cancer. From their experiments in animals, it would seem possible that during the pre-metastatic reaction period the resistance of the individual may be increased by reinoculation of the tumor, or possibly of products of the tumor, to such an extent that the resorption of the original tumor may be brought about.

The Importance of Active Muscular Exercise in the Restoration of Function.—C. Hermann Bucholz considers to what extent active exercise may be used in the restoration of function, and how much we may expect from it. He examines the relation of nervous and muscular function and the effect of functional treatment in lesions of joints and bones. He also considers the importance of active exercise in the diseases of the circulatory system, and some other internal diseases. The best orthopedic surgeons maintain that active exercise should never be neglected in any case of scoliosis. The special value of active exercise and its advantages in many cases over massage and passive exercise or forcible manipulation is not sufficiently recognized. The following are the special advantages of the active exercises: They are by far the best way to increase tone and strength of the muscles; they have a mechanical effect on the tendons, the function of which can be improved but never entirely restored by massage. The most important effect which active exercises produce is the restoration of normal joint action. Active movements are valuable, therefore, in restoring the function of joints, by their early use preventing much of the loss of function which results from long use of fixation methods. Among the internal organs the function of which may be restored, or at least improved, by gymnastics should be mentioned especially the lungs and pleurae. The principles of such exercises are the following: Strengthening the respiratory muscles to promote deep breathing, in order to force all parts of the lungs and pleurae to take part in the function, and also to improve the circulation in the lungs. Deep inspiration, together with resistance movements of the trunk and upper extremities, will favor the expectoration in chronic bronchitis and loosen adhesions in pleuritis. Among other diseases which are amenable to active exercise treatment may be mentioned diabetes, obesity, and constipation. In the future many conditions in which heretofore reliance has been largely placed upon drugs will be found to be satisfactorily amenable to treatment along the line of active muscular exercises. More lasting results may be expected from these methods which call into action the restorative and conservative forces within the human body itself.

New York Medical Journal, August 14, 1909.

On Some Technical Difficulties in the Distention Method for Hypospadias and Other Urethral Affections.—Carl Beck gives a retrospective view of his experience in those cases of urethral malformations, defects, and injuries which he has treated after his principle of

urethral distention. The most important of his observations is, that even in the scrotal type success was obtained by employing the method of forward dislocation. It is not advisable to leave a *cathéter à demeure* longer than five days because incrustations soon form and the caliber of the catheter becomes obstructed. The necessity of leaving a catheter *in situ* is an evil. Whenever, therefore, its use can be avoided it should be left off. It must be appreciated that just one of the great advantages of the distention method is supposed to be that the catheter can be dispensed with. It is never too early to perform the operation for hypospadias, and it is nothing less than criminal negligence to let a hypospadiac grow up to manhood without operating upon him. Constriction of the penis by an Esmarch bandage was never found necessary; temporary pressure by a small gauze compress suffices to control the hemorrhage. As far as failures of the distention method are concerned, it seems to him that they are more due to the hand than to the method itself. The most frequent mistake made is that the urethra is not sufficiently mobilized. Careful observation of the diet is imperative for the first four or five days. Large doses of potassium bromide are in order.

The Presence of Tubercle Bacilli in the Urine of Tuberculous Patients, Their Significance and Dangers.—E. J. G. Beardsley concludes that: (1) Acid and alcohol fast bacilli are frequently present in the urine of tuberculous patients. (2) Such bacilli have been proved in many instances to be capable of producing tuberculosis in animals. (3) Until it is conclusively proved that these bacilli are not virulent it is wise to consider all of them virulent. (4) It is reasonable to believe that in tuberculosis, tubercle bacilli are present, at times, in the blood of the individual. (5) Tubercle bacilli may be present in the urine without a macroscopical lesion of the genitourinary organs. (6) Although inoculation experiments are absolutely necessary to prove conclusively that a germ found in the urine is the specific bacillus of tuberculosis, nevertheless a bacillus that retains the carbol fuchsin stain after thorough decolorization with Pappenheim's solution is likely to be the tubercle bacillus. (7) Disinfection of the urine and feces of tuberculous patients is required to free them from danger of transmission of the disease to others.

The Analogy of Migraine to Rheumatism.—J. N. Cohen says that it is evident that the question of the etiology of migraine is far from settled. Some admit that it is due to an intoxication, or that there are periodic sensory discharges of the brain, or that there is a vasomotor neurosis; but even if one admits all these theories to be correct, he is still ignorant as to the direct exciting cause of these nervous disturbances, advanced as explanations of migraine attacks. If we combine any of these theories with that of a rheumatic toxemia, we have an exciting cause which will be initiative for the various nervous phenomena by which these attacks are explained. By combining all three, *i.e.* a rheumatic intoxication, a "brain storm," and a vasomotor neurosis, we have a vasomotor disturbance, caused by an intoxication acting centrally upon the brain and causing periodic discharges, and thus indirectly acting on the vasomotor system. In summarizing the various medicinal measures employed in the preventive treatment of migraine attacks, it may be stated that the various coal-tar products have been prescribed with more or less success. Cannabis indica, caffeine citrate, and ergot also have their advocates. Treat the patient exactly as you would if he were suffering from an acknowledged rheumatic affection. Salicylic acid and its preparations stand pre-eminent, and when rightly employed are a most valuable remedy.

Some Observations on Inflammation of the Veru Montanum.—John A. Hawkins says that inflammation of the veru montanum is usually due to gonorrhea affecting the deep urethra, and as probably 90 per cent. of all patients suffering with gonorrhea acquire an extension to the posterior urethra and many of them to the seminal vesicles and epididymes of necessity by way of the ejaculatory ducts, it is surprising that the veru montanum should escape as often as it does. The most common symptom of which the patients complain of is pain in the anterior two inches of the urethra; it is of a stinging or burning character. In some cases there is a frequent deside to urinate; also a marked tenesmus with the appearance of blood with the last drop of urine. The urine to-day may be full of shreds and to-morrow absolutely clear. Irritation of the sexual apparatus is usually marked. The use of silver nitrate will be followed by results if intelligently used. With a solution of 15 or 20 per cent. the swollen veru is promptly reduced in size. These solutions are readily borne and are extremely useful when properly used in the various stages of these inflammations.

Journal of the American Medical Association, August 14, 1909.

Breast Feeding.—M. Ostheimer says that it is uncommon nowadays to see any attempt made to induce the mother to nurse her child, even when the breast milk has not been examined to see whether it is abnormal or not, and asks if this is not chiefly the fault of the medical adviser. This is the case not only three or four days after birth, but later when the child is between three and six months old, breast feeding is often stopped for no apparent cause. He quotes authorities who have advocated the persistence in breast feeding and examination of the mother's milk in behalf of the infant. He says that in his experience he has found that much can be accomplished in aiding and inducing the mother to continue nursing both at the beginning and when the infant is several months old and stopping has been considered. He urges the continuance of breast feeding until the baby is at least eight or nine months old. During the last few months of pregnancy not only should the nipples receive daily attention, but the habit of drinking water should be cultivated and the woman should learn to be able to drink two or three quarts a day. Exercise in the open air, a full amount of sleep and a nap during the afternoon, correct wholesome food, and attention to the regularity of the bowels are essential. After delivery it is most important that the mother take daily several quarts of water, some with meals and a great deal between meals. Tea and coffee should be prohibited during lactation. The thin corn meal gruel recommended by Southworth is next in importance and properly flavored it can be made a very agreeable food. If the woman likes milk she should take it, but it should not be forced on her, and cocoa prepared with milk may be substituted. As before delivery, exercise, fresh air, sufficient sleep, etc., are necessary. Most medical men prefer not to allow nursing in advanced tuberculosis and there is a kind of urban, nervous woman in whom all efforts to improve her milk supply are apparently wasted. Dr. Southworth's suggestion to give the child both breasts temporarily, alternating with one or two bottles a day when the mother first begins treatment, will be of value in some serious cases. He gives his experience in treating these cases of deficient milk supply and tapering off from breast feeding. While special stress is laid on feeding, the ordinary hygiene must not be neglected, the child as well as its mother receiving due attention as regards this point. Ostheimer's object in writing this paper is to reiterate the immense importance of breast feeding and to report his experience in successfully urging its continuance and overcoming difficulties, few of which are found as real as the young mother thinks them.

Middle Milk Mixtures.—A. H. Hess says that it is some years since it was shown that when milk is allowed to stand, the bacteria are carried upward with the fat globules so that the cream layer contains a vastly greater number of microorganisms than the underlying skim milk. In a laboratory study, published about a year ago, he demonstrated that the bacteria in the cream are not uniformly distributed but are present in far the greatest number in its upper surface. He then suggested the use of these principles in infant feeding and showed how after discarding the upper two ounces of cream the proper percentages could be obtained. His suggestion, however, seems not to have found general acceptance, though it has not been criticised so far as he has noticed. He therefore again calls attention to it, after a personal experience of almost a year with this method, and points out that it is not merely an interesting laboratory suggestion, but a practical modification of top milk feeding possessing decided advantages. He gives the instructions which he has used with mothers of only average intelligence, but who readily understood them and utilized them. They were directed to remove the upper two ounces of cream and reserve it for table use, then dip off the next eight ounces of milk, which furnishes them the standard 10 per cent. cream which they are directed to dilute with water or barley water, according to the age or condition of the child. He does not urge this as a substitute for pasteurization or sterilization, but simply as a suggestion of bettering whatever milk is used.

Infantile Diarrhea.—C. G. Grulee concludes that true dysentery in infants must be relatively rare in Chicago. He says there are many reasons for believing that the

B. dysentericus is not etiologically connected with a large percentage of the diarrhea in infants. In the first place, the cases showing this organism in the stools showed no clinical differences from those in which it was absent. In the second place, the dysentery bacilli were usually few and hard to find, and, in the third place, agglutinins were by no means constantly present, as far as could be learned, and the antidysenteric serum seemed to have no effect. The dysentery bacillus has never been cultivated from the blood of these infants nor has it ever been found outside the human body, except in the laboratory animals. He therefore regards the connection of the dysentery bacillus with the summer diarrhea still, at least, an open question, with the burden of proof on those who assert its etiological relationship. Since the infectious nature of the disorder has not been proved, we must seek elsewhere for its causes. Within the past year Finkelstein has described a disorder of nutrition which he calls metabolic intoxication. The symptoms are the same as those of summer diarrhea as we encounter it. He has proved that this disorder is caused primarily by the inability of the organisms to properly assimilate sugar, a condition to which too much fat in the food predisposes. Czerny and Keller, while agreeing with Finkelstein, to a certain extent, suggest that we may have a toxicosis due to the decomposition of the food by bacteria, either before ingestion or in the gastrointestinal tract. Grulee, after discussing the condition and pathological findings, comes to the conclusion that while infection in the intestinal wall probably occurs in some cases, it is not the usual cause of a summer diarrhea in infants, but that this infection is, as a rule, due to disturbance of metabolism or to decomposition of the food. As regards treatment, it is evident that, if this is the case, the first indication is to stop the food and put the child on a low diet. This is not all. There must still be a supply of fluid for the system and this we accomplish by giving barley water or weak tea. It is occasionally impossible to give this by the mouth, and it is well to resort to a continuous enema or even to a subcutaneous administration of normal salt solution. After ten to forty-eight hours of the starvation treatment, it is time to give the patient food, the symptoms having usually disappeared. For the past two years he has usually employed skim milk as the first food for these children. He has ,as a rule, had this boiled, which kills the bacteria and seems to be more readily digested. This skim milk is given in the amount of one and a quarter to one and a half ounces to the pound weight of the child, each twenty-four hours, and diluted sufficiently to afford the proper quantity at each feeding. This is a temporary measure and, as soon as possible, milk sugar must be added and whole milk substituted for the skim milk. The condition of the child must be the guide. The greatest trouble with this method is the tendency to constipation when the skim milk is being replaced by whole milk, and the addition of malt may be useful. The vomiting may continue and require stomach washing and bismuth in extreme cases. Reduction of temperature can be accomplished usually by the measures already suggested, but hydrotherapy is often useful. The distention which occurs only in the more protracted cases can be temporarily relieved by the introduction of a tube into the rectum, the other end of which is placed in a vessel containing hot water. We may also use colonic flushings and hot external applications to the abdomen. Collapse can best be met by mustard packs, followed by saline infusion and continuous saline enema. Grulee does not favor the use of calomel in these cases and he believes it has been much abused. As for intestinal antiseptics generally, he sees no indications for them in these cases.

Calcium Salts in Epilepsy.—A. P. Ohlmacher has hitherto refrained from publishing his remarkable success following his first trial of the calcium salts in epilepsy, but now since Littlejohn (Lancet, May 15, 1909, page 1382) has reported results with the same agent, he wishes to supplement it with his case. It was a child four years and four months old, with no heredity of epilepsy, in whom the disease had begun and continued from a month after his third birthday. When first seen he was having from 34 to 73 attacks a month and his mental growth had apparently stopped. The *grand mal* attacks as seen by Ohlmacher were very severe, but never became the typical full status epilepticus. The child had frequent nosebleed following these attacks and its nurse asserted that she could detect the odor of blood on the breath during convulsions and prior to the appearance of actual hemorrhage. At the time Ohlmacher had been working on therapeutic immunization, where the problem of blood coagulability presented itself, and he had employed Wright's method of measuring the time of blood coagulation and of using calcium salts to fortify a defective coagulability. Accordingly, when his attention was called to the hemorrhages, he made a blood clotting test and, finding that it was slow in clotting, he began giving calcium lactate in doses of seven to ten grains dissolved in hot water and added to the milk three times a day. This medication has been continued from this first beginning, on June 2, 1907, with no change, except occasionally reducing to one or two doses daily, to the present time. The coagulation time was soon reduced to normal and since the cessation of the epilepsy, three months after commencing the calcium lactate, the child has had occasionally nasal hemorrhages apparently related to periods of lowered coagulability. At the time he began the medicine McCallum's observation on calcium metabolism as related to parathyroid intoxication and to tetany had not been published, nor had Carle's paper on calcium chloride in therapeutics appeared. Incomplete observations on several additional cases similarly treated tend to confirm the favorable results with the first case.

The Lancet, August 7, 1909.

A Method of Giving Ether by Means of Nasal Tubes.—H. M. Page says that this method of giving ether, which was devised by Crile of Cleveland, deserves further trial and to be better known. The apparatus consists of two India rubber tubes sufficiently large to fit closely the nares, these nasal tubes are coupled to a much larger India rubber tube by means of a Y-shaped piece of glass tubing; this large India rubber tube is connected with a large glass funnel which is covered with a single layer of thin flannel, and it is interrupted in its course by a glass trap to prevent any excess of ether running down the nasal tubes. Ether anaesthesia is induced by the open-drop method; the mouth is then opened, and the pharynx and pharyngeal aspect of the epiglottis and larynx are brushed over with a solution of cocaine, and the closely fitting nasal tubes are pushed down the nares till the lower ends are opposite the epiglottis. The pharynx is then packed with gauze. Ether anaesthesia is now maintained by the drop method on the flannel covering the glass funnel.

Pressor Bases in Normal Urine and Their Diminished Excretion in Gouty Urine; the Excretion of Chlorides in Gout.—William Bain offers the following summary: (1) Normal urine contains two bases which produce a rise of blood pressure. (2) The first of these was originally discovered by Abelous and termed by him "urohypertensine." It can be obtained as an oxalate from an ethereal extract of the urine. It is volatile with steam and is probably identical with isoamylamine, a base which is formed from leucine. (3) The second base remains behind after extraction of the first base with ether, and it can then be obtained by extracting with amylic alcohol, the urine made alkaline with sodium carbonate. Its reactions indicate that it is identical with, or allied to, *p*-hydroxyphenylethylamine, a base which is formed from tyrosine. (4) Both bases are obtained during the putrefaction of proteins. The existence of pressor basic material during the putrefaction of flesh was discovered by Abelous. The identification of the bases is the result of Rosenheim's work on putrefying placenta and of Barger and Walpole's on putrid meat. (5) Their presence in the urine is explicable on the hypothesis that they are formed by putrefactive processes in the alimentary tract; they are then absorbed and excreted in the urine. (6) In the gouty urines so far examined by the methods of Abelous and steam distillation the first base is entirely absent. By the "direct method," however, a pressor base was present, but the rise in blood pressure caused by it was much less than that produced by a similar extract from normal urine. The amount of the second base in gouty urine was smaller than in normal urine. The decrease in the elimination of these bases will possibly explain the rise in arterial blood pressure frequently observed in gouty patients. An investigation was undertaken to find out if defective elimination of the urinary chlorides was a feature of chronic gout, and also to ascertain the response of the kidney in gout to an increased amount of work. The results show that in gout the output of chlorides probably balances the intake, and that the kidneys in the two cases under consideration performed their work in a satisfactory manner; in fact, behaved as normal organs.

The Relative Toxicity of Chloroform and of Carbon Tetrachloride.—Augustus D. Waller says that chloroform is a reagent of great toxicity; according to his observations, 100 times that of ethyl alcohol. Carbon tetrachloride has a toxicity about double that of chloroform. Hair-wash, of which the principal ingredient is carbon tetrachloride, has a still greater toxicity. The carbon tetrachloride present in the wash is, in his opinion, sufficient to cause the death of a healthy person apart from any question of fatty heart or adenoids or status lymphaticus. The cloud of heavy vapor by which the head might be enveloped would necessarily be more or less abundantly inspired, and a very few inspirations of such a highly poisonous vapor would suffice to cause drowsiness or sleep, and might be expected sooner or later actually to cause death.

British Medical Journal, July 31 and August 7, 1909.

A Case of Pseudo-Diphtheria Due to the Pneumococcus.—P. Hamilton Robertson reports the case of a girl, eight years of age, who was admitted to the hospital certified as suffering from diphtheria. Her breathing was rapid and labored, she was distinctly cyanosed, and had a hoarse cough. Her temperature was 102°, and pulse 140. Both tonsils were thickly coated with a whitish membrane, and she coughed up some thick, whitish material. On inspiration there was considerable epigastric retraction, and on auscultation there was evidence of widespread bronchopneumonia in both lungs. In view of the obstruction to respiration, tracheotomy was performed. The membrane seemed softer than usual, so a smear was made which, on examination, showed a pure culture of what was morphologically the pneumococcus. The case was then diagnosed as one of bronchopneumonia, with tonsillitis and laryngitis due to the pneumococcus. The patient was desperately ill, but recovered. She was greatly relieved during the first two days by the administration of oxygen.

Inoculation for Chickenpox.—Donald Smallpeice reports that two of his children having had severe attacks of chickenpox, he decided to inoculate the third, a girl of eleven years, hoping that possibly the eruption might be modified, and the period of incubation possibly shortened. On the second day of the eruption he opened a vesicle on the back of the child, aged four, and inoculated the older child over the biceps of the left arm. Antiseptic precautions were taken, and the scratch disappeared on the third day. Eight days later the site of the inoculation became irritable; on the following day there was a slight raised papule, looking as though a small vesicle had been rubbed off. There was no fever nor constitutional disturbance. Later in the day she became violently sick and feverish. The following day her temperature was 100°, and there was a general acuminated papillary eruption, with a scarcely visible vesicle at the apex. The fever disappeared on the second day, the spots were fading, and the patient was quite well in five days' time. The interesting point is that the eruption was so modified as to show no likelihood of pitting, and the incubation period was apparently much shortened.

A Plea for a Rational Puerperium.—F. W. N. Haultain gives a fair trial to what he considered a rational management of a physiological process, and the mode of management adopted was as follows: The puerpera, if willing, was encouraged to sit up in bed to meals on the second day. As early as she felt inclined thereafter she was allowed to leave her bed and walk to the fireside, where she sat for an hour. On the following day this was repeated, morning and evening. The next day two hours, morning and evening, were spent out of bed, the patient sitting and walking a little if she so desired. The fifth day after rising was practically spent out of bed, with the exception of a few hours' rest in the afternoon, and on the tenth day the patient left the hospital. The number of patients who followed this line of treatment was 100, all of whom sat up in bed on the second day; 40 rose on the third day; 35 rose on the fourth day; 25 rose on the fifth day. Of the 100 cases, 47 were primiparæ and 53 multiparæ. The morbidity in these cases was represented by three cases. Two developed infective temperatures on the third day. In one there was considerable varicosity of the veins of the legs. All the patients examined six weeks and more after confinement showed involution to be thorough and the position of the uterus to be normal, with the exception of two, being those previously noted as having retroversion. It was most interesting to hear the uniformly eulogistic terms in which, without exception, the women described their so-called convalescence, while the favorable comparisons made by multiparæ with their former confinements was most convincing.

Two Cases of Head Nodding in Infants.—Two such cases are reported by Cameron Gibson. It was suggested that the disease might be of reflex origin, a result of dentition, but neither of these cases leans any support to that view, as their cessation was not marked by any eruption of teeth and the first case was evidently not yet entering on the period, while the second was almost at its close. Rickets has also been suggested as a causative factor, but it was certainly absent in these cases. Raudnitz and J. Thomson have contended that it is due to the dim light in which these babies are living and trying to use their eyes, and this theory fits these two cases well: the seasonal incidence, in the darkest months of the year; the environment, both these babies living during the day in dark ground-floor rooms, with one window facing east, but shut out from most of the sky by tall buildings within a few yards, and neither baby was in the open air. So far as could be found out, the two babies had never been in contact, but their homes were less than fifty yards apart.

Clonic Spasm of the Diaphragm Associated with a Cervical Rib.—G. Bertram Hunt reports the case of an anemic, undersized girl of sixteen years, markedly neurotic, who first presented herself on account of a hard lump in the left posterior triangle of the neck. There were neither pressure symptoms nor scolosis, so no operative treatment was recommended. Three weeks later she was suddenly seized with clonic spasm of the diaphragm, which persisted night and day and was practically uninfluenced by treatment. The diagnosis was a cervicle rib causing irritative pressure on the phrenic nerve. The rib was removed and the patient made a perfect recovery. The spasm of the diaphragm ceased as she passed under the influence of ether, and has never returned during the two years that have elapsed since the operation. There would appear to be two ways in which a cervical rib might cause diaphragmatic spasm: (1) By pressure on the vagus in the neck, causing a reflex contraction, much as derangement of the stomach may produce the ordinary hiccough by irritation of the terminations of the vagus in the gastric mucosa; or (2) by so exalting the normal impulse regularly passing down the phrenic nerve to produce the usual inspiratory contraction of the diaphragm by direct irritative pressure on that nerve trunk as to produce a violent spasmodic contraction of the muscle. The latter appears to him to be far the more probable explanation.

A Method of Temporarily Removing Color-Blindness.—G. Arbour Stephens contends that the cells of the retina move in one direction in response to a red stimulus, and in another in response to blue, while failure to move in any certain direction means failure to convey to the brain the result of a color stimulus. With regard to the sensation of white, he holds that color-blind persons respond to that sensation because the total or complete movement of the cells is produced by a process of contiguity, which overcomes a sluggishness of response to any individual color. Anything that would improve the movements of the cells ought to have the effect of stimulating the retinal cells to more ready response to color sensation, and as the calcium salts have that stimulating effect on the body cells, he comes to the conclusion that a big dose of calcium lactate ought to remove color-blindness, if only temporarily.

Berliner klinische Wochenschrift, July 19 and 26, 1909.

The Increased Blood Pressure in Nephritis.—Gotthelf Marcuse discusses the theories of the cause of the increased blood pressure occurring in chronic nephritis, and proposes a new theory. It has been shown that partial nephrectomy causes an increase in blood pressure, whereas unilateral or bilateral total nephrectomy does not. Furthermore, a partial clamping of the renal artery also causes an increase in pressure. The renal artery has a collateral branch which supplies the suprarenal gland. Any factor which causes an increased resistance to a flow of blood through the kidney, be it a clamping of the vessel, obliteration of a portion of the vessels by partial nephrectomy, or a chronic nephritis, causes for purely physical reasons a shunting of blood into the suprarenal branch, an increased flow of blood to the suprarenal gland, a hyperemia, and resultant hypertrophy, and hyperactivity of the gland. The result of this is an increased secretion of adrenalin into the blood, and increase of blood pressure.

A New Theory of the Cause and Treatment of Chronic Constipation.—Lipowski has noted for years that a normal person is able to retain his intestinal contents one, or even more, days longer than usual without causing marked change in its consistency, while if a person suffering from chronic constipation does so the stool very quickly becomes extremely dry and hard. This he considered must be due to an abnormal power of the colon to absorb water in these cases. He tested this by injecting 200 c.c. of physiological saline into the rectum of healthy and constipated persons, syphoning it off in fifteen minutes, and measuring

the amount returned. He found that whereas from a normal rectum 30 to 90 c.c. would be absorbed in that time, from the rectum of a constipated individual as much as 150 to 180 c.c. would be taken up. From these observations he evolved an "absorption coefficient" for his patients consisting of the fraction found by the amount of fluid absorbed divided by the amount injected. Considering chronic constipation to be due to a high absorptive power of the colon, he endeavored to find some method of reducing this. Oil injections seemed hopeful, as they would prevent water absorption by covering the intestinal wall with oil. The difficulty with this lay in the fact that while a few injections of oil are well borne, after a time the patients are unable to take it, due to the decomposition of the oil in the intestines, and the resultant irritation. In the effort to find a substitute for oil which had not this objection, the author hit upon paraffin. By mixing one part of paraffin of a melting point of 78° C. and eight parts of fluid paraffin he obtained a paraffin melting at 38° C. His procedure consists of the injection of 200 c.c of this, warmed to fluidity, through a soft rectal tube inserted 20 cm. into the rectum. The advantages of paraffin over oil are: (1) It is not necessary for the patient to remain recumbent for hours, as it is after an oil injection, as the paraffin immediately becomes of an ointment-like consistency, and remains in the bowel. (2) The paraffin does not irritate the bowel, and may be retained over night with almost no discomfort. (3) It is not decomposed, and so decomposition irritation does not occur. (4) It does not, like oil, produce flatus. (5) The action is prompter than oil. (6) Owing to its lack of irritating properties it can be used for a prolonged time. He has used paraffin in 53 cases, 46 times in the evening, and 7 times in the morning. Of the 46 cases, 44 had good spontaneous movements in the morning, and the other two following a water enema. In the seven cases treated in the morning results appeared in the afternoon.

Ulcerative Meningococcus Pharyngitis.—F. Reiche reports a case of acute pharyngitis with extensive exudation and ulceration occurring in a case of meningitis. From the exudate and the spinal fluid the meningococcus was grown, but the blood cultures were sterile. From the pharynx was also grown the streptococcus. The author suggests that possibly the meningococcus is able to produce pharyngitis only in the presence of streptococci.

The So-called Psychoreaction of Much.—Zaloziecki agrees with other observers that the Much-Holzmann reaction is not specific for dementia præcox and cyclic insanity. He finds, on the contrary, that it is dependent upon muscular activity. In men muscularly active it is present; in those quiet it is absent. In epileptics during and just following convulsions the reaction is positive; between attacks it is negative. In some it is negative in the morning, positive towards evening. He believes the reaction is due to sarcolactic acid in the blood, which in a strength of one-sixteen-hundredth normal will completely prevent the hemolysis and in one-sixty-four-hundredth normal will definitely delay it.

Münchener medizinische Wochenschrift, July 6, 20 and 27. 1909.

The Antitrypsin Content of the Blood in Gynecology.—Becker reviews the literature of the estimation of the antitryptic action of the blood and reports a series of observations on gynecological cases. In 1908 Brieger and Trebling showed that in cases of carcinoma the blood serum contained some substance which had the power of preventing the digestive action of trypsin on albumin. They showed further that, while the reaction occurred also in other illnesses in which there was much destruction of albumin, it was constantly present in carcinoma only. They used the method of Müller and Jochmann for estimation of leucocyte ferment, namely, the formation of depressions in Loeffler's blood serum plates on spots where the leucocytes had been placed. These authors had shown that while one part of normal serum mixed with four parts of a 1 per cent. trypsin solution would cause digestion of the Loeffler's blood serum plates that in using the serum of carcinomatous patients of 35 examined it required over ten parts of trypsin to one of serum in 23 cases and as low as six parts to one in only four cases. Also the antitryptic action was present in 14 cachectic but noncancerous cases. Von Bergmann and K. Meyer improved the technique by applying Fuld's method of estimation digestion, namely, the digestion of casein and using this instead of the gulley formation or Loeffler's plates. They found interference of trypsin digestion power in 90 per cent. of the cancer cases. This method was cheaper, quicker, and more accurate. It consisted in placing in each of a series of test tubes 2 c.c. of a 0.2 per cent. casein solution and 0.5 c.c. of a 2.0 per cent. serum solution, and 0.1 per cent. trypsin solution in increasing amounts from 0.1 c.c. up to 1.2 c.c. After one-half hour in the thermostat at 37° five drops of a 5 per cent. solution of acetic acid in alcohol and water was added to each tube. If a precipitate occurred, the digestion of the casein was incomplete; if the solution remained clear, it was complete. When normal serum was used all tests in which from 0.1 to 0.4 c.c. of trypsin solution was used were incomplete, and all of 0.5 c.c. and over complete. The minimal amount which would usually digest the definite amount of casein was therefore 0.5 c.c. of trypsin solution, and this amount was taken as a normal standard. If a larger amount of trypsin solution was required to digest the casein antitrypsin was considered to be present in proportion to the amount of solution required. This was essentially the method used by Becker in the present researches. In 20 cases of cancer he confirmed the Brieger-Trebing findings of an increase of antitrypsin, 0.7 c.c. of trypsin solution being the smallest amount which would digest the casein. In 14 cases it was greatly increased, 1.0 c.c. or over, and in one case 1.6 c.c. In a second series of 55 cases with various diseases, not carcinoma, 14 showed the increase of the antitryptic action to 1.0 c.c. or over. Three of these were markedly cachectic, four had extensive abscesses, and two cystitis. The third series comprised 30 pregnant women. In one-half of the cases the "index" of 0.7 or less was found, and in only one case did it reach 1.0. This patient was one of secondary anemia. The serum for the fourth series was taken at the end of labor, just after the delivery of the placenta. Of these 30 cases only four were as low as 0.7 c.c., five definitely increased, 0.8 c.c. and 0.9 c.c., and 21 markedly increased. The highest, 1.5 c.c., was in a case of eclampsia. The author summarizes his results as follows: In the blood of patients with carcinoma one finds fairly constantly a great increase of the antitryptic power. This is, however, not specific for cancer, as it occurs with other diseases (anemia, chronic septic processes, and cachexia) and immediately after childbirth. The increase of the antitryptic action may be used in diagnosis in conjunction with other clinical symptoms. It has no very great diagnostic significance, as the reaction is often positive by anatomically benign, clinically malignant tumors. With childbirth a marked increase of the antitryptic power occurs, whereas during pregnancy it is either normal or only slightly raised.

The Clinical Significance of Antitrypsin in the Blood.—L. Jacobs reports some observations on the antitryptic action of blood serum in a series of 100 cases. Fuld's method of estimation of the ferment action was used. (See above.) He designates the amount of trypsin required to digest the casein without the addition of serum, as $\frac{a}{a^1 V}$, and the amount of trypsin required when the serum was added as $a^1 V$ and calculated the antitryptic power of the serum i from the formula $i = (a^1 V - a)\frac{100}{a}$. He draws the following conclusions from his investigations: An increase of the antitryptic ferment of the blood serum occurs in a relatively large number of various diseases. It is apparently constant in marked cachexia, is especially frequent in all diseases associated with a change in the leucocytes, and finally in a number of cases in which one can determine none of these relationships. The nature of the reaction and the reason for its occurrence are too obscure and its positive appearance too common in different diseases for it to be used as an aid in diagnosis.

The Much-Holzmann Reaction.—In two papers on this subject one by Fraenkel, Kathe, and Bierotte, and the other by Beyer and Wittneben, the authors show that the Much-Holzmann, so-called psychoreaction is not specific for dementia præcox and manic depressive insanity, that it occurs in only about one-half of such cases, while it is present in a large proportion of cases which are not of these types. For example, in epilepsie in 60 per cent., and in idiocy in 74 per cent. of the cases examined.

Biocystography.—Lichtenberg, Dietlen, and Runge describe a method of taking x-ray photographs of the bladder during various stages of its contraction. By this they found that from all sides a simultaneous continuous motion occurs, which begins slowly, and increases in speed toward the end of micturition. As the longitudinal diam-

eter decreases more and quicker than the horizontal the powerful longitudinal muscles would appear to contract quicker and more strongly than the circular fibers.

The Physiology of the Milk Secretion.—Cramer says that the development of the mammæ is dependent upon the functioning of the ovaries. He reports two cases in point. The first was a case of sexual infantilism in a woman of 31 in which the breasts were entirely undeveloped. In the second case a girl of 21 years, with infantile genitalia and a history of complete amenorrhea, there was also apparent lack of mammary tissue. In this woman implantation of ovaries from another woman caused the appearance of regular menstruation and the definite development of the breasts. From this he concludes that the growth of the breasts at puberty is dependent upon some material produced in the functioning ovary. As the woman from whom the ovaries in the above transplantation were taken was pregnant at the time of the operation, and was able, after the birth of her child, to nurse it for many months, though both her ovaries had been removed, Cramer says that the puerperal enlargement of the breasts and the lacteal secretion is unrelated to the ovaries. He then considers the etiological factors of the puerperal milk secretion. He refers to cases in which, both at the time of intrauterine death and much later at the delivery of the dead fetus, milk secretion appeared, and to another in which, after an abortion at the eleventh week, the woman served for many months as a wet nurse. The discontinuance of metabolic interchange between mother and child may cause the lacteal stimulation. Starling caused breast hypertrophy in rabbits by repeated injections of emulsions of rabbit fetuses, while emulsions of ovaries, uterus, and placenta, were without effect. It is probable that the presence of a living fetus influences the growth of a gland capable of secretion, while the ending of the metabolism of pregnancy gives the stimulus for the milk secretion. The author then considers the effect of suckling. Pregnancy is not aboslutely necessary for milk secretion. Occasionally milk secretion appears in virgins at the menstrual period. Sellheim has shown that by the laying on of an infant during pregnancy the milk secretion can be produced, and Kehrer that repeated suckling of the male breast will cause it to swell and secrete a rich supply of milk. When a woman has been obliged to stop nursing for several weeks and the milk supply has dried up, the returning of the infant will often cause a renewed secretion. From these facts Cramer concludes that we must recognize a definite relation between the act of suckling and the functioning of the breast, and that the mammary gland at the end of puberty becomes definitely dissociated from the other genital organs, and that when suckling calls for it, it can take up its functions without the influence of any other stimulatus.

Deutsche medizinische Wochenschrift, July 22 and 29, 1909.

Sudden Death and Trendelenburg's Operation for Pulmonary Embolus.—Busch discusses the applicability of Trendelenburg's operation for removal of pulmonary embolus in cases of sudden death, and reports a series of such cases. Of 9,727 cases treated in the surgical side of his hospital, there were 878 deaths, 22 of which were sudden, or 2.3 per cent. In 12 of these death occurred instantaneously, so that operative interference was out of the question. In the other 10 cases the death occurred within between ten minutes and three hours. In four of these, at autopsy, there was no embolus found, and in five more it was of such a character as to make operation impossible. It is very difficult in cases of sudden death to make a diagnosis between pulmonary embolus and myocardial heart failure. It is also impossible to tell whether the embolus, if it is present, is in a situation where it can be removed or is near the periphery of the lung, and so inoperable. His conclusions are that in cases of pulmonary embolus morphine must be given first of all to control the stormy dypsnea, and then intravenous injections of digitalin. In the meantime everything must be prepared for operation, which shall be performed as soon as it is shown that other means produce no improvement. The general condition of the patient must be considered. In men with severe septicemia, marked arteriosclerosis, or extreme cachexia one would hardly attempt such a procedure.

Coxa Valga Rhachitica.—Stieda reports a case of this condition in a boy of eight, and refers extensively to the literature. He says that an important symptom is the difference in the length of the thighs without raising of the trochanters. The latter is further from the anterior superior spine on the side of the lengthening. On account of the dissimilarity in the length of the legs and the greater loss of function in the more effected side, the patient stands on the shorter leg with the longer one slightly bent at the knee. The gait is characteristic. The spastic condition seen in other coxa valga cases is wanting. The symptoms resemble congenital dislocation. There is insufficiency of the gluteus medius and minimus with definite Trendelenburg's phenomenon owing to the abnormal proximity of the points of insertion of the muscles. The therapeusis is medico-mechanical. Especial attention must be paid to strengthening the hip muscles by massage, passive resistance, and exercises in standing and hopping on one leg.

Treatment of Cardiospasm.—Makkas reports two cases of long-standing cardiospasm with marked dilatation of the esophagus. This diagnosis was confirmed by *x*-ray pictures by the use of bismuth. In treatment he used gradual dilatation of the cardiac orifice by means of Gottstein's dilator. This consists of a balloon in three layers, the inner and outer of rubber, and the middle of silk. The inner balloon is so reinforced with rubber that with slight dilation it is spindle formed, and on stronger dilation it becomes cylindrical. The balloon is passed into the cardiac opening and then, by means of a tube, attached to it, dilated with water. One case was treated for one month, the other for two months, with strikingly good results, so that the patients who had swallowed fluid only with great difficulty were able to take solid food with ease.

Treatment of Multiple Abscesses in Infants with Specific Vaccine.—Wechselmann and Michaelis treated a series of infants with furunculosis with staphylococcus vaccine and conclude that the treatement of multiple abscesses in infants with this is to a high degree specific. The estimation of the opsonic index is unnecessary. As a rule, a polyvalent staphylococcus vaccine appears to be satisfactory, and it is only in exceptional cases that the vaccine must be made from organisms from the patient.

Recurrens Paralysis in Beriberi.—Miura reports a case of a twenty-year-old man with beriberi, in whom, beside paralysis of the extremities, the facial nerve, and the internal organs, bilatteral recurrens paralysis occurred, and on microscopial examination changes were found in the N. vagus, the N. recurrens, and the laryngeal muscles.

French and Italian Journals.

Relations Between Purpura and Hematopoiesis.—G. Jone reports a case which shows the relation between progressive hemorrhage with spastic anemia, and intestinal disturbances in purpura. Most intestinal purpuras are of bacteriemic origin, and micotic embolism is demonstrable. Only degeneration of the arterioles was demonstrable in this case. The study of this case and of those reported in literature show that purpura hæmorrhagica should be considered as a derangement of two functions, the toxoinfective and the hematopoietic. These two factors may exist alone or be combined in etiological relation. Purpura acts differently according to which element predominates. In the ordinary form the infective manifestations are severe and accompanied by necrosis, but hemorrhage alone will not generally cause death. But when there is uncontrollable hemorrhage the hematopietic element is most important, and it should be sought in clinical and anatomical characteristics.—*La Riforma Medica,* June 21, 1909.

Treatment of Malignant Tumors by High-Frequency Currents.—J. A. Rivière believes that high-frequency currents applied with the Oudin apparatus or after the method of Keating-Hart should be used after every operation for malignant disease to cause the elimination of any remains of the growth. In deep growths the treatment is of no use until after operation, since it cannot reach the tumor on account of its depth. On superficial growths and especially on ulcerated surfaces it has a selective action on the malignant cells. It is of the utmost value in epitheliomas and slow-healing wounds. It causes the elimination of the malignant cells and a cicatrization that is prompt and permanent, and without deformity. The author has also used it in tuberculosis.—*Annales d'Electrobiologie et de Radiologie,* May, 1909.

Elongation of the Uterine Nerves in Woman.—Keiffer says that by movements of the uterus between the two hands we may stretch the various structures of which the uterus is composed, rendering them more supple. This is one of the most valuable methods of treatment of uterine difficulties. The entire uterus can be moved between the hands. The posterolateral borders of the organ in which are grouped in bundles the vessels, nerves, and muscles are acted upon and the nutrition is changed. The dominant characteristic of these tissues is plasticity. One of the frequent causes of pain in the genital organs is a lack of elasticity be it the result of congestion, of subinvolution after labor, or of sclerosis. The author explains carefully how the various movements intended to stretch the uterine tissue are made, giving direct to and fro movements of the uterus, and movements that cause it to twist on its access.—*La Gynecologie,* May, 1909.

Book Reviews.

TUBERCULOSIS. A Preventable and Curable Disease. Modern Methods for the Solution of the Tuberculosis Problem. By S. ADOLPHUS KNOPF, M. D., Professor of Phthisio-Therapy at the New York Post-Graduate Medical School and Hospital; Associate Director of the Clinic for Pulmonary Diseases of the Health Department of New York, etc. New York: Moffat, Yard & Co., 1909.

THIS book is intended primarily for the education of the laity, and as such is admirably adapted to its mission for more than one reason. It comes from one whose authority on the subject is so unquestioned that his unwavering optimism is like a call to victory for the race. Dr. Knopf is far from minimizing one iota of the dread details of this frightful scourge; he knows it from its insidious beginnings to its fatal end, but his whole book is written to show that it need have no beginning, or, if too late for that, that it may be balked of its end; in short, it is both "preventable and curable." In all medical works addressed to the laity it takes a steady hand and a clear head to steer accurately between the Scylla of Radicalism and the Charybdis of Conservatism, and this feat, it need not be said, Dr. Knopf is brilliantly equal to. His style is of the clearest; it would be as impossible for the plain man to misunderstand him as for the literary to fail to enjoy him. He frankly gives to the public all necessary data for both the recognition and cure of tuberculosis, and at the same time leaves no doubt as to the need of the physician at the helm. It is shown with the utmost clearness that tuberculosis is essentially a disease for self-help, but not for self-treatment, and that in all such matters as diet, exercise, and medication the sufferer needs the constant care and guidance of a physician whom he is willing to trust and obey. Dr. Knopf outlines with a vivid clarity all his own the duty of every member of the community in this crusade, and ends on a note of splendid optimism, that coming from such a source may well put heart and hope into the most fearful.

We have spoken of the work as addressed to the laity, and so it is, but it is full of sound teaching that will be of benefit to the medical man as well, not only in refreshing his memory and bringing him up to date as to the most approved methods of treatment, but also in aiding him in the tactful handling of each individual case. From the technical point of view, the chapters on the adaptation of the sanatorium treatment to the home, and the institution of open-air treatment in any climate, are especially to be commended. They offer, both in text and illustrations, one expedient after another for keeping the tuberculous patient out of doors day and night, many of them applicable to the poorest tenement dwellings and the most crowded neighborhoods. In short, it may be said that this little book, of less than 400 pages, embodies the work of the world as regards tuberculosis, and completely covers the ground of prevention, treatment, and cure, for both physicians and the laity.

THE PRACTICAL MEDICINE SERIES. Volume III. The Eye, Ear, Nose, and Throat. Edited by CASEY A. WOOD, C.M., M.D., D.C.L.; ALBERT H. ANDREWS, M.D., and GUSTAVUS P. HEAD, M.D. Chicago: The Year Book Publishers, 1909.

THIS book is a synopsis of the literature of the year 1908, dealing with diseases of the eye, ear, nose, and throat. Owing to the limited space, most of the subjects have received only brief mention. The authors have noted all the important advances made in their departments, and in no case has clearness been sacrificed to brevity. In every instance the original papers have been mentioned, so that by referring to them a more extensive study of any subject can be easily made. The book will be of help to the practitioner and student who wishes to keep informed of the advances made in the diagnosis and treatment of these specialties.

THE FAITH AND WORKS OF CHRISTIAN SCIENCE. By THE WRITER OF "CONFESSIO MEDICI." New York: The Macmillan Company, 1909.

READERS of "Confessio Medici" (and what physician has not read it?) will look forward with pleasure to reading this book; nor will they be disappointed. The author divides his work into nine chapters, as follows: Philosophy and Christian Science, The Christian Faith and Christian Science, Life and Christian Science, The Reality of Disease, The Reality of Pain, Testimonies of Healing, Opposing Testimonies, "Common Sense" and Christian Science, and Authority and Christian Science. An important part of the work is that containing two hundred consecutive "testimonies of healing" from the *Christian Science Sentinel*. Some of these show the diagnostic laxity of the Christian Scientist, some his lack of the sense of humor, many others are tragic, some are pathetic, and most make amusing reading. Samples of diagnostic acumen are "bowel trouble," "heart trouble," "nervous trouble," or some other "trouble," "dreaded fever," "organic difficulty," "minor ailments," etc. One man's wife was "sentenced to die by materia medica," but was healed by Christian Science. A man was healed of a most serious nervous disease; later, on a steamer, he was not seasick, but, he naïvely adds, he had never been seasick before. The author sums up this part by saying that Christian Science embellishes what she publishes, evades investigation, and that her claim to cure organic disease breaks down under the most elementary rules of criticism. Elsewhere we find reference to a case of pregnancy, where a Christian Scientist "conceived by thought, and no man entered into the case." But physicians and laymen should read this book and see for themselves how these self-styled scientists bully dying women and let babies die in pain; let paralytics tumble about and hurt themselves; let appendicitis go on to septic peritonitis, gastric ulcer to perforation of the stomach, nephritis to uremic convulsions, and strangulated hernia to gangrene; watch, day by day, while a man or woman slowly bleeds to death, and withhold from all cases of cancer all hope of cure. "To these works of the devil they bring their one gift, wilful and complete ignorance, and their 'nursing' would be a farce if it were not a tragedy."

SELF-CONTROL AND HOW TO SECURE IT. (L'Education de Soi-Même.) By Dr. PAUL DUBOIS, Professor of Neuropathology in the University of Berne, Author of "The Psychic Treatment of Nervous Disorders," "The Influence of the Mind on the Body," etc. Authorized Translation by HARRY HUTCHESON BOYD. New York and London: Funk & Wagnalls Company, 1909.

IN view of the fact that there is a widespread interest among the general public in the study and dilettante discussion of functional nervous disorders, we are glad to welcome a popular yet strictly scientific book, by a medical authority, dealing with the prevention of such disorders on the basis of mental control. Professor Dubois's first book, "The Psychic Treatment of Nervous Disorders," was well received and widely read in the United States, and continues to be an authority on the subject. The present volume comprises a series of brief essays, all bearing on what self-control may accomplish and how it may be secured. Among the topics thus discussed may be mentioned: The conquest of happiness; thought; conscience; education; egoism and altruism; indulgence; moderation; patience; courage; chastity; kindness; idealism. The style of the book is charmingly direct and philosophical. Numerous anecdotal illustrations and interesting cases are cited, and it is readily understood how the lack of self-control may be a very great factor in the production of nervous disorders. The author agrees with Dumas *fils*, who said: "How does it happen that while children are so intelligent, men are so stupid?" and answered his own witty question by adding: "Education must be responsible for it." The text of the author is obtainable from a quotation: "Now, judgment is just what we need in life—a clear view of things, enabling us to foresee the immediate and the future consequences of our acts." We commend the book to physicians and to the intelligent lay reader, to both of whom it will be helpful and suggestive in the prevention of what "need not have been and should no longer be possible."

GRUNDRISS DER KLINISCHEN DIAGNOSTIK. Von Dr. med. GEORG KLEMPERER, Universitätsprofessor in Berlin, Dirigierender Arzt am städt. Krankenhaus Moabit. Fünfzehnte, neubearbeitete Auflage. Mit 2 Tafeln und 53 Textfiguren. Berlin: Verlag von August Hirschwald, 1909.

THE popularity of this handy volume on clinical diagnosis is shown by the fact that fifteen editions of it have been called for since its first appearance. It contains brief but ample directions for complete examination of the patient, including rules for getting the history of his disease, for judging the physical evidences obtainable at the bedside, and, finally, for the laboratory study of the various secretions and excretions. Numerous illustrations are used by the author to elucidate the text, especially in the sections upon laboratory diagnosis. We miss, however, pictures of malarial parasites that certainly deserve to be represented more than various microorganisms, such as staphylococci, sarcinæ, etc., to which a colored plate is devoted. The book is, on the whole, most successful in fulfilling its purpose of giving the student a practical and brief guide of clinical diagnosis. It has been translated into English, Italian, Russian, and other languages, and can therefore be used as a textbook by students speaking any of these.

Society Reports.

AMERICAN ACADEMY OF MEDICINE.

Thirty-fourth Annual Meeting, Held at Atlantic City, June 5 and 7, 1909.

THE PRESIDENT, DR. HELEN C. PUTNAM OF PROVIDENCE, R. I., IN THE CHAIR.

The Value of the Nurse in the Public School.—Dr. THOMAS A. WOODRUFF of Chicago read this paper, saying that, while primarily the work of the school nurse was for the promotion of cleanliness and the prevention of disease, her services were valuable in a field of very wide scope. The results of her work showed a decrease in the spread of contagion, instruction of the parents and children in cleanliness and personal hygiene, instruction of the mother in the care of her children, and in the benefits to be derived from cleanliness, fresh air, and right living, assistance to the medical inspector in reporting conditions found in the homes. Cases of privation and disease in the home were often discovered which, uncorrected, would render useless the work of the medical inspector in the school.

The Rational System of Medical Education Will Furnish Physicians Adequate for the Entire Field of Medical Practice.—Dr. LEARTUS CONNOR of Detroit, Mich., said there was need for a system of education to train two classes of doctors, viz., the family physician and the unlimited practitioner. The only rational standard for judging a system of medical education was its fitness to supply those products that best met the needs of the entire medical field. It was suggested that the organized profession determine exactly what the family physician could be trained to do, and how much, in each simple disease and the beginnings of the complex, without interfering with like training in any other disease. A rational system called for teachers trained in the profession of teaching as well as in that of medicine, and institutions saturated with the pedagogic spirit, method, and practice. It was the clear obligation of the organized profession to promote the evolution of such rational system of medical education.

Classification of Exceptional Children as a Guide in Determining Segregation.—Dr. MAXIMILIAN P. E. GROSZMANN of Plainfield presented this paper, suggesting a tentative classification of exceptional children, a brief outline of which was: (a) Normal children: (1) Typical children; (2) pseudo-atypical; (3) atypical. (b) Subnormal children: (1) Defective children; (2) children of arrested development; (3) children of rudimentary or atavistic development. (c) Abnormal children. No classification, however, could differentiate all individuals. He thought it extremely difficult to determine a normal standard so as to preclude ambiguity. Deviations from the normal standard did not invariably imply a corresponding decrease of usefulness for human progress. In the classification the children termed "pseudo atypical" need little or no segregation, these being helped by special or ungraded classes. From the special class the pseudo-atypical might be speedily returned to the ordinary classes. Too often, he thought, a purely medical cure was considered. For example, in a case of removal of adenoids, the child might require very expert educational treatment for a considerable length of time after the medical cure. In the atypical group neurotic and neurasthenic children were said to require temporary segregation, or at least education in special schools, where their entire life could be remodelled. In the subnormal group those merely incomplete or defective were regarded as most encouraging. Children whose development was permanently checked before maturity were not considered in the symposium. It was suggested that redemption through prevention might come in the next generation, the same being true of children of rudimentary or atavistic development.

The Necessity of Expert Medical Inspection of Public Schools.—Dr. ALBERT RUFUS BAKER of Cleveland said his paper was an attempt to define exceptional children not needing segregation. The school teacher's opinion of what constituted an exceptional child he regarded as often erroneous. Frequently would the teacher credit the myopic child with more gray matter than obtained, while the bright child suffered from hyperopia, astigmatism, or adenoids, might be regarded as a dunce. Often the school teacher who assigned impossible tasks, rather than the pupil, needed medical supervision. The medical inspector should be especially trained and should devote his entire time to the work, and he should not be a recent graduate and given a few hundred dollars a year for making perfunctory visits to the schools. In Cleveland a salary of $600 annually was paid the school physician, thus attracting a better class of men. The employment of expert examiners who should devote their entire time and energy to the work offered the only solution to the author.

The Leakage in Our Educational System.—Miss MARGARET BANCROFT, President of the Training School at Haddonfield, contributed this paper, which was read by Mr. Farrington of Haddonfield. The familiar phenomenon of some children failing to advance normally was referred to. The final result was a leakage of educatable material into the streets, the jails, and the custodial schools. A close study would show that practically every case of slow advancement was due to physical disability. The work of saving these children the handicap of imperfect education or the calamity of custodial life was primarily the duty of parents and teachers. An understanding of elementary physiology, psychology, hygiene, etc., should be required of every person who assumed the responsibility of parenthood or undertook to rear and educate children. Ignorance of the elementary facts of life, growth, and education on the part of parents or teachers might result in grave injury to the children. The medical profession must bear the responsibility of a large part of this ignorance which exists. We were in the habit of speaking of the mentally defective children as if the real mind of the child were at fault. The defect would be found in the injured cortex, the undeveloped association fibers, the broken axis-cylinders, the blighted sensory organs, or the weak metabolic processes, and not in the higher faculties which composed the personality. We needed organized and systematic instruction of parents by physicians. We needed really practical courses in physiology, psychology, hygiene, etc., conducted by able physicians, in the curricula of our normal schools. We needed experimental laboratories in connection with our public school systems, in charge of fully trained persons, competent to examine children who deviated from the normal work or progress of the regular grades, and to plan and execute efficient special methods of training to correct this deviation. We needed better taught and wider read physicians. Above all, we needed a more optimistic spirit in handling the exceptional children that difficult cases might not be pronounced hopeless and packed off to custodial schools, which was little short of criminal. The people needed to be taught the truth about these things, and the opportunity to give such instruction was in the hands of the medical profession. When adequate knowledge had been imparted, the work of stopping the leakage in our educational system would be an easy task, for enlightened public opinion was all-powerful.

Care of Exceptional Children by the Children's Bureau of Philadelphia.—Dr. WALTER S. CORNELL and Mr. J. PRENTICE MURPHY contributed this paper, which was read by Mr. Murphy. It was a study of seventy cases out of 6,824 children considered by the Bureau for care during 1908. Two important underlying principles were said to be: The superiority of the private home over the institution as an environmental influence, and the basic normality rather

than abnormality of the exceptional child. The second principle was proven first from the standpoint of the physician, as those children showed no particular stigmata other than those due simply to neglect, such as squint from hyperopia, high palates from adenoids, flat chests from nasal obstruction, or poor nutrition. Active types of exceptional children, those with excess of physical energy, but no training, were said to require rather long training, which training was best given in an institution. Backward children (defective intellect plus temperamental eccentricities) were said to need bracing in institutions as a rule, but could be provided for at times in family homes direct. For morally difficult children little scientific work was being done. There was at the present time no good institution for this class of children. Those cases standing in immediate need of strict discipline were said to be best treated in private homes, but that this was attended with so much cost as to be unwise. Difficult girls presented a more serious problem than boys, and were better cared for in institutions, in most cases. Causes of exceptional children in the family were given as irregular occupations, lack of training, and ignorance, drunkenness outside the family, bad housing, inadequate and poorly adjusted school facilities, and lack of playgrounds. Of the 70 children forming the basis of the paper 49 had improved, 12 being returned to their own homes. Of the 21 not improved, 12 were sent to disciplinary institutions for further treatment and 9 are still in their own homes.

What Is Being Done for Backward and Mentally Deficient Children in the Public Schools of Philadelphia.—Miss Lydia A. Kirby, Director of Schools for Truants, Incorrigible, and Mentally Defective Children, stated that a systematic attempt to help backward and mentally deficient children was the result of efforts of Miss Margaret Bancroft of the Training School of Haddonfield, N. J., member of the Civic Club of Philadelphia, and Miss Dora Keen of the Public Education Association. In 1901 the Board of Education took hold of the movement. At present they had twenty-one classes. The sessions lasted from 9 until 2 P.M. Nature study was given prominence. Each school was provided with a shop containing twelve work benches, with tools, and some pupils who could not remember their spelling did good work with their tools. Other pupils had raffia, cardboard, chair caning, basket making, and hammock making. The training of the muscles at the dictation of the mind was one of the most valuable ways of helping these children. Sense-training exercises were used for those who were most defective, and special exercises were employed to correct defective speech. Music was a daily exercise, and physical training was given in the school yard. The school physician visited the class daily. The chief value of the teachers lay in their character and disposition. They must possess unlimited sympathy and patience. A record of the work showed conclusively that apparently hopeless cases of physical inability, moral and mental deficiency, might be partly or wholly overcome, under adverse school conditions, with the aid of devoted teachers. The study of defective children should form a part of the work of every normal school.

What May Be Done for Exceptional Children by the Training of Speech and the Development of Language.—Dr. G. Hudson Makuen said that speech bore somewhat the same relation to the mind that the hammer and saw did to the carpenter. It was the mind's most effective and most important tool, being not only the vehicle in which the products of the mind were transfered and delivered, but it was essential also to the creation of these products, to their crystallization, collection, and classification. If one trained and perfected a person's speech one would greatly improve his mentality. Defective speech was both a physical and mental sign of feeble-mindedness, but it was by no means a pathognomonic sign, and it might be a cause and not a result of the feeble-mindedness. Of 5,000 examinations of exceptional persons, observation and treatment ranged from several weeks to as many years. The examinations included individuals and ancestral histories, and mental and physical investigations. In a series of five cases reported the children were all suffering from arrested speech development, with a resulting corresponding arrest of mental development or an abnormal mental development. In the first four the patients were under treatment for more than a year, and the results had been most satisfactory. Only one of the children had made any attempt to talk, and his speech was a mere jargon. They were now all talking freely and quite intelligibly, and had, moreover, freed themselves entirely from the charge of feeble-mindedness. In the fifth case there had developed some evidence of faulty cerebration. Aside from the direct mechanical means that were employed for the restoration of hearing, treatment consisted entirely in the training of the faculties of speech. Four other cases reported illustrated what might be done for children who were exceptional on account of certain psychophysical peculiarities, one of the chief symptoms of which was defective speech, and they also illustrated the fact that speech training was probably the most direct and effective method of developing the human mind.

The President's Address.—Dr. Helen C. Putnam of Providence, R. I., delivered this address, taking as her subject: "American Characteristics and Professional Responsibility." The variations between American traits noted by Tocqueville and other critics of the 40's, and by those at the end of the century, showed many to be transitory, others more permanent or increasing. These last needed the patriot's study. The census and other statistical reports showed that we had grown from an infant among nations to a leader or rival in value of exports, suicides and insanity, inventions, murders without convictions, multimillionaires, fatalities, and other accidents of transportation and industries, national wealth, infant mortality, developed natural resources, wastefulness of timbers, waters, mines, and animal life, vastness of business combinations, increase of vice, social diseases, divorce, school population and educational institutions, vagaries in religion, psychology, economics and medicine, manufactures, wage-earning children, tramps, unemployed and unemployable, numbers and excellence of sociologic movements for social betterment. Our mistakes were chiefly due to ignorance of and indifference to life, including as a result greed and indifference to law. The medical profession was logically responsible for removing this fundamental obstacle to worthier ambitions —ignorance of biological facts, phenomena, and laws— ignorance more profound since we were so rapidly to become a nation of city dwellers. What a few public school instructors were beginning to do wisely the profession should give its utmost support to forwarding. The advance of physicians themselves depended at this stage very much more on a better preparatory foundation than it did on any alterations in medical courses, much as the latter were needed.

Division of the Fee and Commission to Physicians.—Dr. Augustus A. Eshner of Philadelphia observed that the physician's fee varied with the requirements of the individual case and with the skill and experience of the practitioner; that the service should be adequately compensated, and equally so if a second physician were summoned. He believed there could be no honorable division of the physician's fee. To make such a division, or for a medical man to pay or receive compensations, would be comprising and demoralizing both to donor and recipient and at the same time disadvantageous to the patient. Nor should commissions be accepted by physicians for articles purchased by patients from druggists, instrument makers, and other tradesmen.

Payment of Commissions by Specialists to General Practitioner.—Dr. E. Gard Edwards of La Junta, Col., contributed this paper, which was read by Dr. Henry B. Hemenway. It was claimed that from the practice of many leading surgeons the custom of fee splitting had spread to almost every specialty, even in minor referred cases, until apparently it was a general practice, even among men of high reputation, especially surgeons, and said to be more common in the West than in the East. The existence of the custom, he said, was rarely mentioned in medical literature, almost never in medical societies, and discussed among the profession with bated breath. To the "horde of embryo specialists abroad in the land, increasing the already sharp competition," he partly attributed the condition. He declared fee splitting to be justifiable when a general practitioner had charge of the case before and after operation, and then only when the patient, physician, and consultant have a full understanding as to the gross amount of the fee to be paid from beginning to end. No amount of regulating by societies, he felt, would control the evil.

A Celebrated Malpractice Suit, 1821-1826.—Dr. James A. Spalding of Portland, Me., related the lawsuit of Lowell of Lubec, Me., *vs.* Drs. Faxon and Hawkes of Lubec and Eastport, Me., saying that it had probably given rise to more discussion and literature than any other ever before the public and the medical profession of New England. Lowell had been thrown from horseback and injured by the horse falling back upon him in 1821, suffered from an alleged hip-joint dislocation, was maltreated and neglected, as he claimed, by the above physicians; consulted Dr. John Collins Warren of Boston, was operated upon by him and the staff of the Massachusetts General Hospital, and obtained from those physicians, under legal threats, affidavits inculpating the Maine physicians. After three extended trials the case was thrown out of court and for four years afterward publications concerning both sides were widely distributed. The case was unique in that long afterward a post-mortem was made, something so far undiscovered in other malpractice suits. It was also interesting that no one of the many physicians involved had made an absolutely correct diagnosis. The writer had discovered the hip-joint involved, and half-tones were shown in conjunction with the paper.

Congregational Practice.—Dr. A. L. Benedict of Buffalo thought the trouble with contract practice to be, in the ordinary sense, largely due to the fact that the premium is not calculated at an adequate rate to provide satisfactory attendance for an average incidence of cases. He felt that, from the standpoint of the laity, the service was unsatisfactory because, with few exceptions, the man who accepted contract practice at a loss would not discharge his obligations in good faith. In addition, acceptance usually implied incompetence or the disposition to self-advertisement. From the standpoint of the medical practitioner the contract physician was regarded in precisely the same light as any other worker who lowered the wage scale. While certain fallacies were obvious in the Chinese method of paying the physician to keep his patients well, the fact was recognized that the value of the physician as an educator and conserver of health would be much greater than according to the Occidental method of summoning him only in sickness.

Contract Practice.—Dr. Charles S. Sheldon of Madison classified contract practice under two general headings: (1) Contracts stipulating a certain sum per year for an indefinite amount of work; (2) contracts stipulating a specified fair remuneration for a specified amount or kind of work. In either class, if the compensation were commensurate with good service, comparing favorably with that paid in private practice, the most serious objection would be removed. The tendency of the whole system, however, was to obtain medical service at the lowest rates regardless of all else. In condemning the practice certain exceptions were suggested as with large corporations in remote and isolated mining or lumber camps. Under proper contracts there might also be excepted railroad, city, or county work, also work for hospitals and institutions and on vessels at sea. These, however, do not constitute exceptions if the contract were awarded to the lowest bidder, with little account given to skill and efficiency. The author thought that the evil could be best controlled by the expression within the profession of a public statement which shall be effective because founded on good sense and justice.

Contract Practice; Its Ethical Bearings and Relations to the Lodge and Industrial Insurance.—Dr. H. T. Partree of Eatontown, N. J., said that the only form of expressed contract to which a physician should become a party was that in which substantially his whole time was taken up in a special work concededly for the public interest, or at least one which imposed no conditions out of harmony with the general aims and high calling of his profession. The bane of contract practice was the desire to get the best of a bargain. There were many phases to the lodge problem in its relation to the physician. Merit and the public weal certainly were not given prior consideration in connection with this contract feature of the lodge. Regarding the relation of the physician to industrial insurance, he contended it was not to the dignity of the profession that its members should be expected to hustle around from pillar to post for 25 and 50 cent fees to see applicants in their own homes because they could not be counted on to walk ten rods to get the insurance. Besides, it was usually necessary to see these cases on Sunday—a most objectionable feature. His remedy was that all applicants should go to the office of the examiner or local superintendent. Once the public learned that insurance would not be so expensive if they did a little seeking, instead of letting the agent do it all, it would not take them long to find the examiner's office.

Contract Practice in Rhode Island.—Dr. George S. Mathews of Providence said that for convenience lodge practice might be classified according to (1) private clubs, (2) lodges and fraternal organizations, (3) works, or shop organizations. In discussing the subject of lodge or contract practice with a large number of medical men who engaged in it, he had found that there were but few ardent advocates of the system. In canvassing the members of the Rhode Island Medical Society it was found that nearly every one was opposed to the system. While the strongest advocate admitted that there were some evils connected with the system, the severest critic would concede that under certain conditions there might be some good in the method. The remedy the writer would suggest was that proposed tentatively by a committee of the British Medical Association several years ago: "(1) Let there be lodges or fraternal insurance companies, but have the doctor paid a fee, even in bulk, more in proportion with the work done; (2) let the membership in these organizations be limited to those whose wage is incommensurate with the needs of the family; (3) have the medical management of the lodges in the hands of the local medical society or a committee of the society; (4) have those physicians who are willing to do this work form a directory from which the individual lodge member may make his selection of his physician."

The Physician in Contract Practice with the Mutual Benevolent Societies.—Dr. A. Ravogli of Cincinnati said that contract practice for the physician offered different aspects and was not to be summarily discarded. The mutual benevolent societies usually employed young physicians, but well trained and of reputed skill. It was in their interest to have their members well attended and soon recovered, that the sick benefits might cease. If the contract called for merely a nominal remuneration, with heavy duties, this was debasing of the profession. If the condi-

tions were such as to leave freedom to the physician to treat only the members of the benevolent society, and exact payment for the other members of the family, the contract practice could not be considered injurious to the profession. If another physician entered the society, offering to do the same work for less remuneration in order to chase out the first physician, then the fault lay with the member of the profession and not with the benevolent society.

A Defense of Contract Practice.—Mr. JOHN C. MCMANEMIN of the Fraternal Order of Eagles said that, although the "contract physician" was ostracised by medical societies, the members of these same societies ofttimes entered the field of "contract practice" as assistants to other physicians as family physicians receiving a stated annual compensation, as examining physicians for insurance companies, and various like forms. Commercialism seemed to be the basic principle of opposition to "contract practice." The deprivation of fees was hidden under the shallow mask of lowering of professional ethics and cheapening of medical knowledge. The "contract physician" had a fixed income, obtained a large and varied experience from the heterogeneous practice, and enjoyed confidential relations with a large portion of the community in which he resided—a foundation upon which many a successful practice rested and to which many a physician of prominence to-day could attribute his success.

Why Not Make Contract Practice Universal?—Dr. WOODS HUTCHINSON of New York City declared the present system of medical attendance to be a makeshift and an anomaly. "Born in an emergency and tinkered up at odd times," it had never been properly planned out or thought through. It combined the maximum of expense to the patient and of loss by all sorts of accident to the doctor, with the minimum of health production and of prevention. He asked, Why not take advantage of the law of averages, both of mortality and morbidity, arrange a definite scale of fees for yearly attendance per patient and per family, and devote the best of the energies of the physician to keeping the patients well, instead of patching them up after they had fallen sick? Said yearly fee, which could be carefully and accurately worked out by a conference of all parties concerned—laymen on the one side, and physicians, surgeons, and operatists on the other—and adjusted accurately and fairly to the locality, income, and social position of the patient, as well as to the age and length of practice and consequent experience of the medical adviser, should be made to include a thorough physical examination of every member of the family at least twice a year, whether they felt out of health or not, and sanitary inspection at regular intervals of the house, water supply, drainage, and sewage, and conditions of places of work or study of each individual.

Report of the Committee to Draft a Medical Practice Act.—Dr. CHARLES MCINTIRE of Easton, Pa., presented this report, the substance of which was that the essential ideas to be kept in mind in framing a medical practice act were: (1) That the law was for the protection of the people; (2) that it should provide but one executive body to supervise the law; (3) that it should present an accurate definition of the practice of medicine; (4) that it should specify the educational qualifications, both general and professional for the applicant; (5) that the board should have the power to test the applicant to see if he had made proper use of his educational advantages; (6) liberal provision should be made for the representatives of all shades of opinion on the board, not of right, but of policy; mixed boards did not weaken the efficiency of the board; (7) the law should supervise those who had been licensed, revoke the licenses of those who ceased to be safe practitioners, and should have the power to seek out and to punish those who attempted to practise without legal right; (8) it was desirable that a different test should be provided for those who had been in practice than for those just in practice; provision should be made whereby a license could issue after an examination of the record and previous licensure in another State to an applicant without a formal examination of the applicant himself; (9) the members of the board being employed by the State to exercise police duty should be sufficiently remunerated by the State independent of the license fees; these should be put into the State treasury as part of its income; (10) the principles upon which the restrictions of the act were based should be stated with care and exactness, but in such a manner as to give the board the greatest liberty in the execution of them that it might be able to adapt itself to contingencies arising under a rearrangement of conditions; (11) in view of the persistent claims of the osteopath, it may be well to have provisions for a limited license for those desiring to practice only in part.

Report of the Delegate to the Annual Meeting of the Association of American Medical Colleges.—Dr. CHARLES MCINTIRE read this report. Judging from the part of the meeting that he was able to attend, it must have been one of the most successful and profitable of the meetings held under the auspices of the association. The representatives of the various colleges seemed to be sincere and in earnest, and when they differed they differed frankly. With this spirit there was a field for increasing usefulness on the part of the association. It needed the support of some of the stronger institutions, many of which were formerly affiliated with it, although of more rigid requirements than those of the association. The requirements now were such that there should be the helping co-operation of all worthy medical schools. The speaker hoped the Academy would accept the invitation already extended to send a delegate to the next meeting, which was to be held in Baltimore in March, 1910.

Report of the Committee to Arrange a Conference with Educators.—The committee recommended: (1) That the attention of the medical profession be called to the desirability of permitting medical schools to receive properly qualified students into advanced standing for the studies included in the first two years of the medical course, and that they be urged to secure a modification of the law permitting medical colleges to certify to the student's completion of the studies of the first two years, independent of the length of time and residence in a medical college, and that this recommendation be sent especially to the State societies and the boards of medical examiners. (2) That the Council of Education of the American Medical Association be requested to formulate the preliminary and graduation requirements of the medical course in terms of work done after due consultation with educators and others interested, as suggested by the paper of Dr. Jackson. (3) That the Academy record as its opinion that there was great danger to the college of arts in our country from the prevailing idea that it was not a place for earnest effort on the part of the student. Unless there was a change in the purpose of those pursuing the college course there was danger of the impairment of the usefulness of the college for all but the idler. (4) That the Academy appoint a committee to formulate the requirements of admission, preserving the principles underlying the present wording, but adapting them to the educational procedure of the day.

Election of Officers.—*President*, Dr. James H. MacBride of Pasadena, Cal.; *Vice-Presidents*, Dr. Philip Zenner of Cincinnati, O.; Dr. W. Blair Stewart of Atlantic City, N. J.; Dr. Ruth Webster Lathrop of Philadelphia, Pa.; Dr. H. W. Loeb of St. Louis, Mo.; *Secretary and Treasurer*, Dr. Charles McIntire of Easton, Pa.; *Assistant Secretary*, Dr. Alex. R. Craig of Philadelphia.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting Held at Philadelphia, June 3, 4, and 5, 1909.

THE PRESIDENT, DR. C. B. G. DE NANCREDE OF ANN ARBOR, IN THE CHAIR.

(*Concluded from page 335.*)

Suprapubic Prostatectomy.—Dr. ARTHUR DEAN BEVAN of Chicago said splendid results had been obtained by performing both the suprapubic and perineal operations, and, considering the ages of the patients upon whom these operations had been done, the mortality was low. Suprapubic enucleation of the prostate had the widest field of usefulness. All things considered, the cure was more complete by the suprapubic than by the perineal route. The suprapubic was less dangerous and less formidable than extensive perineal dissection. There was no injury done to the musculature or perineum by the suprapubic route; there was very little danger of injuring the rectum, and little probability of stricture or fistula following.

Dr. A. J. OCHSNER of Chicago said that he who had done prostatectomy both perineally and suprapubically a number of times must be impressed with the great ease with which the prostate can be enucleated from above. He had removed a large number of prostates by the perineal route, and quite a number by the suprapubic, and had been impressed with the simplicity and ease with which the operation could be done suprapubically.

Dr. ALEXANDER HUGH FERGUSON of Chicago said his first twenty-five cases of prostatectomy were operated on by the suprapubic route. Of this number he lost eight. He disliked to return to that method, and now resorted to the perineal route. One could operate on almost any enlarged prostate successfully through the perineum. If accurate statistics were collected it would be found that the mortality was twice as high by the suprapubic as by the perineal route.

Dr. JOSEPH RANSOHOFF of Cincinnati said the mortality from the suprapubic operation could be greatly reduced if we made perineal drainage by means of a puncture from above.

Dr. MAURICE H. RICHARDSON of Boston had seen a good many surgeons operate for the removal of prostates, but never saw one who could see what he was doing to the urethra. Speaking as an anatomist, he had never been able to tell whether he was tearing the urethra to pieces or not when operating perineally or suprapubically. Other surgeons had told him the same thing. The mortality came from the advanced age of patients, and not from the operation *per se*.

Dr. S. STILLMAN of San Francisco had a decided preference for the suprapubic operation, where the urine was healthy and where it could not be rendered healthy the mortality from the suprapubic or perineal operation could be overcome by following a suggestion which had been made by Sir William Macewan.

Dr. A. PRIMROSE of Toronto said his experience had been confined principally to the suprapubic route. Infection of the pelvic cellular tissue was the cause of mortality in some cases in which the suprapubic route had been resorted to. It seemed feasible to remove the prostate by the transperitoneal route in some cases, and, if necessary, establish perineal drainage.

Dr. JOHN B. MURPHY of Chicago had operated on the prostate first by the perineal route, and then the suprapubic. Finally, from an experience of 123 cases he found he could take out the small, firm, hard prostate more easily and safely from below; while the large, thick, juicy prostate he could remove easier and with greater safety to the patient from above.

Dr. LEONARD FREEMAN of Denver suggested a method of controlling hemorrhage in cases of suprapubic operation.

Dr. MOORE, in closing on his part, said that he expected in five years from now to hear Dr. Bevan read a paper on the complications and sequels of suprapubic prostatectomy. Dr. Murphy stood on solid ground, in that he fitted the operation to the case in hand, and did not try to make every case fit one particular operation.

Dr. BEVAN, in closing, said the evidence was quite conclusive in favor of the suprapubic operation from the standpoint of completeness of the cure and the freedom from complications.

A Study of One Hundred and Thirty-One Consecutive Cases of Fibroid Tumors of the Uterus Demanding Operation.—Dr. ARCHIBALD MACLAREN of St. Paul, Minn., said that a fibroid tumor of the uterus should be operated upon when it commenced to increase in size or to cause symptoms. He agreed with Richardson that the same rule should be followed as in ovarian cysts or in appendicitis in the interval, but that a small subperitoneal tumor need not be removed if it was not increasing in size. It was not always possible to be sure that a certain tumor was uterine and not ovarian in origin; the usual error was to diagnose a small ovarian tumor as a fibroid, on account of its smooth, hard, solid feel. The subject of this paper was the last one hundred consecutive hysterectomies for fibroid disease and also the myomectomies, thirty-one in number, which had been performed during the same period of time. The question of first importance was the age of the patient. A young woman should always have myomectomy, if possible. After a myomectomy the tumor might reform, or other small growths, which were too deeply buried in the uterine wall, or too small to be palpated, might increase in size, cause a return of the symptoms and necessitate a second operation. This had only occurred three times in his total experience of over sixty myomectomies. Myomectomy had been done during pregnancy four times, with one miscarriage. He would not advise the removal of a uterine tumor producing no symptoms in a pregnant uterus. In regard to the mortality, there had been five deaths in the 131 cases, or 3.8 per cent.; 3 per cent. in the series of one hundred hysterectomies, and two deaths in the myomectomies, making 6 per cent. This looked like an unjustifiable mortality for myomectomy, but as both were accidental deaths in no way due to the myomectomy they ought not to be charged to this operation. The first was due to the giving way of the catgut pursestring suture about the stump of the appendix, which had just been removed. The second death was probably due to the leaking of a gall bladder which had been opened and drained through a stab wound, several gallstones having been found at the time of the operation for the removal of a fibroid tumor. One of the principal dangers of myomectomy, as well as hysterectomy, was post-operative hemorrhage. The gradual formation of a hematocele, which occasionally followed either operation, should be watched for carefully. He had been in the habit of putting in vaginal drainage at the time of the operation when there was any difficulty in preventing oozing. And twice after myomectomy he had made a vaginal section on the third day, opening up and draining such hematomata, with the most gratifying results. In his earlier work he lost two cases where the puddle of pus in the cul-de-sac was due to the infected, brokendown blood clot which had caused the fatal septic peritonitis, discovered at the autopsy. To the recognition and drainage of these accumulations of blood more than to any other one thing did he ascribe his improved results over a few years ago, when he used to find them at the post-mortem examination. The danger of a fibroid tumor producing a suppurative pelvic peritonitis was considerable. In the 100 hysterectomies three came to him with pelvic abscesses complicating the tumor, due either to a perforative appendicitis, to necrosis of the tumor, or to compression of diseased appendages.

In regard to the method of performing hysterectomy, supravaginal amputation had been the operation of choice, and only in malignant disease or a suspected malignancy had he reverted to complete removal of the uterus. This was for two reasons: (1) Because it was a less dangerous operation in his hands, and (2) because he had never seen a fibroid tumor grow in the stump of the cervix after a supravaginal amputation. Large-sized catgut for the vessels, No. 3 or 4, or No. 2 doubled, was the best ligature material. It was awkward for tying the uterine arteries deep in the pelvis, and much greater force had to be used than would be necessary on the surface, so the ligature must be larger and stronger. It was always wiser to cut the uterine arteries beside the cervix before picking them up, for they lay very close to the ureter. The only time that he had ever injured the ureter was in one of his earlier operations, when the uterine artery was ligated *en masse* before cutting the artery.

Dr. Maurice H. Richardson of Boston had had a large experience in operating for the removal of fibroid tumors of the uterus, and felt there was a greater danger attending myomectomy for the removal of multiple tumors than hysterectomy. If you were going to give a patient a most safe procedure in a case of multiple fibroids of the uterus, it was better to do supravaginal amputation. This opinion was based on personal experience after many years of operating on these growths.

Treatment of Tetanus.—Dr. Willard Hunter Hutchings of Detroit, Mich., directed attention to an experimental study of the various methods of treatment of recognized tetanus, and from the results obtained by these experiments he had become convinced that chloretone was the best agent or substance that had been employed thus far with which to control the muscular manifestations of the disease. He had treated six cases that were referred to him with chloretone, with five recoveries. A detailed account of each case was given in the paper. Chloretone had no effect on the toxin circulating in the blood, nor did it break up the combination between the nerve cells and toxin. Its use was harmless. There had been no fatality following its use. It lowered temperature, and had a slight diuretic action.

Dr. Theodore A. McGraw of Detroit said that in one of the cases related by Dr. Hutchings, in which tetanus developed, extreme care was used in thoroughly disinfecting the wound, and when the wound was opened as a matter of precaution against tetanus everything was found aseptic, yet tetanus developed.

Dr. Wm. H. Carmalt of New Haven asked the chemical composition of chloretone.

Dr. John B. Roberts of Philadelphia said that we had all realized for many years in our hospital experience that chloral would cure tetanus, but now, with the addition of antitetanic serum, we had a good combination. He would like to know whether chloretone had any relation to chloral, or whether it was similar in its composition.

Dr. Thomas W. Huntington of San Francisco had used chloral to the limit in three cases of tetanus, and all three patients died.

Dr. A. T. Bristow of Brooklyn emphasized the absolute necessity of putting patients with tetanus in a room by themselves, absolutely quiet and free from noise or irritation of any kind, and recommended the use of chloral and bromides in large doses.

Dr. De Forest Willard said that the only case of tetanus he remembered saving was one in which he kept the patient under chloral for twenty-eight days.

Dr. C. B. G. De Nancrede of Ann Arbor said they had a great deal of tetanus in their section of the country. He had saved the lives of a few patients who had tetanus with chloral. He had never seen any effect from antitoxin after the disease had started.

Dr. Nathan Jacobson of Syracuse, N. Y., said as to the possibility of controlling tetanus by amputation, a review of the literature taught that it had little or no effect. As to the manner of introduction of the antitoxin or serum, whether it was introduced intracerebrally, intraspinally, intraneurally, or intravenously, there was practically no difference in the results.

Dr. John E. Owens of Chicago said the use of antitetanic serum must be considered in the light of a prophylactic. During the constructive period of the World's Columbian Exposition they had several hundred cases of nail wounds of the hands and feet, and in not a single instance did tetanus develop. Their treatment consisted in opening the wounds freely, curetting them, more or less, then applying 95 per cent. carbolic acid, and covering the wound with ordinary surgical dressing.

Dr. J. Ewing Mears of Philadelphia said that in a hospital at Ceylon, at the time he visited there, tetanus of puerperal origin was treated successfully with injections of antitoxin.

Dr. Hutchings, in closing, said that regarding the composition of chloretone, when he began using it he did not know what it was, but was impressed with its beneficial action. He asked a chemist how chloretone was made, and he said: "If you will take equal parts of chloroform and equal parts of acetone, and put them in a test-tube, and boil for a minute or two, then add sodium hydroxide, which precipitates the chloretone—that, when purified, is chloretone." What the chemical composition of it was, he did not know. It was very important to isolate patients with tetanus. Mere amputation, without any other treatment, had no effect whatever on tetanus.

Dr. J. M. T. Finney of Baltimore presented a paper in which he spoke of transporting skin flaps from remote parts of the body from one individual to another. He believed that the application of this principle was feasible.

Surgery of the Large Intestine.—Dr. William J. Mayo of Rochester, Minn., in a paper on this subject, said that anatomically the large intestine was a connected whole, but embryologically and physiologically it could readily be divided at the splenic flexure into two well-defined parts. The proximal half was derived from the midgut and was an important part of the nutritive system, as it absorbed about half of the fluids and 10 per cent. of the solids. The descending colon and the sigmoid were derived from the hindgut, had an antiperistaltic motion, and acted as a fecal storehouse. In the large intestine lymph drainage followed the arterial supply, but the lymphatics were not numerous, and in the sigmoid were very sparse. Mobilization of the large intestine for operation was most important, and could be readily accomplished by cutting the outer peritoneal fold, which did not contain important structures, where it was reflected to the abdominal wall and lifted the gut from its bed. In this way the large intestine could be drawn outside the abdominal incision and the cut ends approximated easily after extensive resections. The inner leaf of the mesentery was very long, extending practically to the midline, and contained the arteries, nerves, and lymphatics. After mobilization the arteries should be tied and divided at their origin, and the entire mesentery with the fat and gland cleanly dissected from the deep structures. The right inferior angle of the duodenum must be identified and separated in operations about the ascending colon and hepatic flexure. The ureters were attached to the peritoneum after crossing the common iliac arteries, and must be isolated, especially on the left side, to prevent injury. If a neighboring organ, such as the small intestine, stomach, bladder, or uterus, was adherent, it should be coincidentally resected, providing the disease was still local. In cancer of any part of the cecum, ascending colon, or hepatic

flexure, all of the large intestine proximal to the disease should be removed with at least six inches of the ileum, and an ileocolostomy performed between the proximal ileum and transverse colon. In cancer of the transverse colon, splenic flexure, descending colon, and sigmoid, union must be made between the two segments of the large intestine, a procedure not so safe as a union between the ileum and colon. It could be made end to end if sufficiently covered by peritoneum, otherwise end to side, or lateral, where the peritoneum was sound. If obstruction was marked, the three stage operation of Mikulicz-Paul was advisable. In low sigmoid cancers the combined abdominal and perineal operation was best. In fleshy males the posterior, and in debilitated females the Quenu-Tuttle operations gave good results in low sigmoid tumors. He reviewed 100 resections, with 12 deaths; for cancer, 61 times, with 8 deaths. Twenty-four were carcinoma of the cecum and ascending colon, with 3 deaths; the transverse colon, including the hepatic and splenic flexures, was removed for carcinoma 7 times, with 1 death; the descending colon and sigmoid were excised for carcinoma 30 times, with 4 deaths. For benign disease, 39 times, including inflammatory disease, tuberculosis, diverticulitis, etc., with 4 deaths.

Resection of the Sciatic Nerve.—Dr. Kenneth A. J. MacKenzie of Portland, Ore., exhibited a patient with molloscum fibrosum, who developed, first, a tumor of the ulnar nerve, which was removed by another surgeon. Subsequently the patient developed a tumor of the sciatic nerve, which grew slowly at first, but more rapidly after traumatism. Severe pain was transmitted to the foot from the pressure caused by the tumor. Operation consisted in removing the sciatic nerve *in toto*, with good result. Patient walked well, considering that the nerve was entirely removed and the nerve supply cut off from the groups of muscles that were involved.

Operative Treatment of Fractures.—Dr. John B. Walker of New York reported six cases on which he operated for the relief of deformity following fractures, with good results.

Dr. William B. Coley of New York reported a case of strangulated retroperitoneal hernia of the intersigmoid fossa, and one very rare (probably unique) case of interparietal ventral hernia at McBurney's point.

Suggestions for the Operative Correction of Syphilitic and Other Deformities of the Nose.—Dr. John B. Roberts of Philadelphia called attention to the importance of the reconstructive surgery of the external nose. He stated that the cosmetic improvements possible were not fully appreciated by medical men or by the public at large. The inherent difficulty in these operations was in obtaining and maintaining sufficient projection of the reconstructed organ and in preventing cicatricial closure of the nostrils. The early recognition of syphilitic lesions of the nasal bones and cartilages and the prompt institution of efficient antisyphilitic treatment would prevent the occurrence of many conspicuous disfigurements. Blows upon the nose in childhood often caused dislocation of the nasal cartilages and bones. These lesions were untreated because of negligence in examination immediately after the injury. The frontal method was probably the best for total rhinoplasty. Brachial flaps might sometimes be used with advantage. Portions of cartilage or periosteum from other regions of the body might be used to give rigidity to the tissues transferred to the nasal region. Paraffin injections into the subcutaneous tissues were sometimes used as an adjunct. Loss of the cartilaginous extenral nose below the nasal bones was probably best repaired by Keegan's frontal method. Nelaton's frontal method, which consisted in incorporating a portion of costal cartilage in the frontal flap, was valuable when the bony nasal bridge was missing. The author's method of repairing the sunken nose of syphilis with flaps from the cheeks and mid-frontal region was described as a successful operation. Suggestions for repairing irregular deformities of various kinds were made in the paper.

A Method of Combining Exploration and Decompression for Cerebral Tumors Which Prove to Be Inoperable.—Dr. Harvey Cushing of Baltimore said that the usual osteoplastic method of exploration of the cerebral hemispheres for a tumor, which, after exposure, proved to be inoperable, was usually transformed into a palliative or decompressive measure by the removal of the osseous layer of the resected flap. This frequently led to undesirable consequences, owing to the unnecessarily extensive protrusion which might occur when the brain under tension was protected by scalp alone. In these cases the bone flap might be preserved and a sufficient hernia, under the protection of the temporal muscle, be provided for, through the removal, while the flap was temporarily resected, of the area of bone which underlay the temporal muscle. Thus the advantage of the usual subtemporal decompression could be combined with the more extensive cortical exploration permitted by a temporary osteoplastic resection.

Unusual Case of Gunshot Wound of the Brain.—Dr. Joseph Ransohoff of Cincinnati in this paper reported a case of gunshot wound of the brain from a 32 caliber rifle. The patient was shot in the right temple in May, 1899. The immediate left-sided hemiplegia which followed the injury disappeared within a year. Three years later general convulsions supervened, the attacks coming on every three or four months, without any focal point of origin being in evidence. The *x*-ray showed the bullet split into three parts, one evidently in the zygomatic fossa, one in the temporal fossa, and the largest fragment just within the skull, on a level with the cribriform plate, and probably in or near the cavernous sinus. Later, left-sided paralysis supervened gradually, but he did not see the case again while alive. Death ensued with coma in twelve hours after the onset of the acute symptoms, nearly ten years after the injury. The autopsy revealed an abscess in the right temporosphenoidal lobe, with a small piece of the bullet firmly encapsulated in the abscess wall. The largest fragment shown in the *x*-ray picture had become innocuous and was found to be embedded in the cavernous sinus.

The following papers were also read: **"The History and Microscopical Study of Fifty Consecutive Cases of Excision of the Thyroid,"** by Dr. Francis J. Shepherd and Dr. Charles E. Duval of Montreal, Canada; **"Sudden Death: A Study of Certain Cases Occurring During Physical Exertion or Psychic Shock,"** by Dr. John B. Blake of Boston; **"Observations on the Inequalities of the Right and Left Femora,"** by Dr. A. T. Bristow of Brooklyn, N. Y.: **"Vesico-Intestinal Fistulæ,"** by Dr. F. W. Parham of New Orleans.

Owing to lack of time, several other papers were read by title, although the authors were present. A rising vote of thanks, which was extended to the local members of the association for their hospitality, brought the proceedings to a close.

Officers.—The following officers were elected: *President,* Dr. Rudolph Matas of New Orleans, La.; *Vice-Presidents,* Drs. J. M. T. Finney of Baltimore and George H. Monks of Boston; *Secretary,* Dr. Robert G. LeConte of Philadelphia, reelected; *Recorder,* Dr. Richard H. Harte of Philadelphia, reelected; *Treasurer,* Dr. Chas. A. Powers of Denver, reelected; *Member of the Council,* Dr. C. B. G. DeNancrede of Ann Arbor, Mich. Washington, D. C., was chosen as the place of the next meeting, in conjunction with the Congress of American Physicians and Surgeons.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF HEALTH OF MISSISSIPPI.

May 12 and 13, 1909.

ANATOMY.

1. Through what arteries is the collateral circulation carried on after ligation of the femoral below Scarpa's triangle?
2. In amputation of the forearm three inches above the wrist, what arteries will it be necessary to tie, and of what are they branches?
3. Name the ganglia connected with the fifth pair of cranial nerves.
4. Name the muscles that move the humerus (*a*) forward, (*b*) backward, (*c*) inward.
5. Describe the diaphragm, its principal openings, and its nerve supply.
6. What bones make up the pelvis? Describe each.
7. Locate and describe the bladder.
8. Name the bones of the ankle joint and give their relations.

PHYSIOLOGY.

1. What are the causes of the apex beat of the heart?
2. Mention the muscles brought into play during the act of deglutition.
3. Describe the function of the ileocecal valve.
4. What effect have strong alcoholic stimulants on the gastric juice?
5. How are the vocal sounds produced?
6. How does the impairment of the function of the kidneys affect that of the skin and lungs?
7. What is the function of the glossopharyngeal nerve?
8. What are the uses of perspiration?

MATERIA MEDICA.

1. Give two derivatives of morphine used in medicine, with dose of each.
2. What are the sources of salicylic acid?
3. What is the source of carbo ligni, and what are its therapeutic uses?
4. Give the composition of (*a*) black wash, (*b*) Dover's powders.
5. Name six drugs containing large quantities of tannic acid.
6. Name and describe three antiseptics useful for internal administration.
7. Name three animal oils, three vegetable oils, and source of each.
8. Give dose and physiological action of tincture of the chloride of iron.

CHEMISTRY.

1. How many elements are there?
2. Describe two experiments showing difference between chemical and mechanical action.
3. Explain difference between metals and non-metals.
4. What are chlorides, bromides, and iodides? Give an example of each.
5. Name and describe an allotropic form of oxygen, and give the symbol.
6. Give the molecular weight, atomic and molecular volume, and density of oxygen.
7. What percentage of CO_2 exists normally in the atmosphere, and what percentage is dangerous to life?
8. What is chloroform chemically, and how is it made?

HYGIENE.

1. Mention six desirable factors in the location of a resort for consumptives.
2. What deleterious gases accumulate in an improperly ventilated sleeping room?
3. How do nitrites and nitrates get into water, and will their presence condemn it for drinking purposes?
4. What physical conditions would render the taking of a Turkish bath dangerous?
5. What gases are most efficient as disinfectants, and how would you prepare the room?
6. What abnormal condition of the eyes is most common in school children, and what habits tend to produce it?
7. What are toxins, antitoxins, and how are antitoxins obtained?
8. What is meant by natural, and acquired immunity? Give an example of each.

PATHOLOGY.

1. What histological changes occur in acute simple inflammation?
2. What are the joint changes in arthritis deformans?
3. How do typhoid and tuberculous ulcers of the intestines differ?
4. What conditions predispose to cerebral hemorrhage?
5. Name the diseases in which you would expect to find spleen enlargement.
6. Differentiate hematuria and hemoglobinuria, and give the cause of each.
7. Give the pathology of acute anterior poliomyelitis.
8. What inflammatory conditions result in enlargement of the lymphatic glands?

OBSTETRICS.

1. Describe the fully developed ovum.
2. What is the composition of the liquor amnii? Give its uses.
3. Describe the development of the placenta.
4. What changes occur in the uterus during pregnancy?
5. Give cause and treatment of vomiting of pregnancy.
6. When and how would you induce premature labor?
7. What complications of pregnancy justify an abdominal section?
8. Name the various conditions which retard or obstruct labor.

SURGERY.

1. Give indication for ligation of an artery in its continuity.
2. What symptoms follow division of the radial nerve?
3. Mention the possible obstacles to the reduction of a dislocation.
4. Give principles of treatment of compound dislocation.
5. Give cause and treatment of delayed union in fracture.
6. Classify wounds.
7. What are the symptoms of cholecystitis?
8. What is a tumor?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF HEALTH OF MISSISSIPPI.

May 12 and 13, 1909.

ANATOMY.

1. The collateral circulation after ligature of the femoral artery below Scarpa's triangle, in Hunter's canal: (1) The external circumflex; with the lower muscular branches of the femoral, anastomotica magna, superior articular of the popliteal, and anterior tibial recurrent. (2) The perforating and terminating branches of the profunda; with muscular branches of the femoral, and muscular and superior articular branches of the popliteal. (3) The comes nervi ischiadici; with the perforating branches of the profunda, and the articular branch of the popliteal.

2. In amputation of the forearm three inches above the wrist, the radial, ulnar, anterior interosseous, and posterior interosseous arteries should be tied. The radial and ulnar are branches of the brachial; the anterior and posterior interosseous are branches of the interosseous (which is a branch of the ulnar).

3. The *ganglia connected with the fifth pair of cranial nerves:* Gasserian, lenticular, Meckel's, submaxillary, and otic.

4. The humerus is moved (*a*) *forward* by Pectoralis major, anterior fibers of Deltoid, Coracobrachialis, and Biceps when forearm is flexed. (*b*) *Backward*, by Latissimus dorsi, Teres major, posterior fibers of the Deltoid, and Triceps when forearm is extended. (*c*) *Inward*, by Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

5. The diaphragm is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad, eliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumbar vertebræ.

The *openings in the diaphragm* are: The aortic, the esophageal, for the inferior vena cava, right crural, and left crural.

The *nerves which supply the diaphragm* are: The phrenics, the lower intercostals, and the phrenic plexus of the sympathetic.

6. The pelvis is made up of: Sacrum, Coccyx, and two ossa innominata (each of which consists of Ilium, Ischium, and Pubis)

8. The bones forming the ankle joint are: Above the lower ends of the *tibia* and *fibula*, with the two malleoli

(the external from the fibula and the internal from the tibia); the above form a mortise to receive the upper convex surface of the *astragalus*.

PHYSIOLOGY.

1. The apex beat of the heart is caused by the sudden hardening of the left ventricle during its systole, and by the heart twisting slightly upon its axis, the apex being brought more forward at the same time.

2. The muscles brought into play during the act of deglutition are: The hyoglossi, styloglossi, palatoglossi, palatopharyngei, azygos uvulæ, tensores palati, levatores palati, stylopharyngei, stylohyoids, geniohyoids, mylohyoids, thyrohyoids, digastrics, constrictors of the pharynx, and the muscles of the tongue.

3. The function of the ileocecal valve is to prevent the contents of the large intestine from passing back again into the small intestine; it is also a barrier against the passage upward of the bacteria which are normally found in the large intestine.

4. Alcohol "promotes the absorption of accompanying substances (sugar, peptone, potassium iodide), and stimulates the flow of the gastric juice. In this matter it acts as do other condiments (salt, pepper, mustard, peppermint), but if there be too great an irritation of the mucous membrane there is less activity (dyspepsia). The rapid absorption gives to alcohol its quick recuperative effect after collapse, and its value in administering drugs, especially antidotes. Alcoholic beverages combining alcohol and flavor promote gastric digestion and absorption, but often stimulate the appetite in excess of normal requirements. Alcohol is burned in the body, but may also be found in the breath, perspiration, urine, and milk."—(*American Text-Book of Physiology.*)

Excessive use of alcohol causes an increase in the acidity, quantity, and total solids of the gastric juice; pepsin is precipitated, albumin is coagulated, and proteid digestion is retarded or inhibited; the movements of the alimentary canal are accelerated; vomiting and diarrhea may be produced.

5. The *vocal sounds are produced* by an expiratory blast of air being forced through the narrow chink between the true vocal cords. The current of air sets these vocal cords in vibration, and these vibrations are communicated to the air in the upper air passages. The pitch of the sound produced depends upon the rapidity with which the vocal cords vibrate.

6. Impairment of the function of the kidneys throws more work upon the skin, which it can only partially perform; some of the work must also be performed by the lungs. If severe or long continued, death ensues from autointoxication.

7. The *function of the glossopharyngeal nerve* is: (1) Taste, to posterior part of tongue and palate: (2) sensation to mucous membrane of pharynx, fauces, and tonsil; it is also claimed that it is (3) motor to the constrictors of the pharynx.

8. The *uses of perspiration* are: Excretion of water, carbon dioxide, and urea; cooling of surface of body, and regulator of heat of body.

MATERIA MEDICA.

1. *Two derivatives of morphine:* (1) Codeine, dose, gr. 1/2. (2) Apomorphine hydrochloride, dose, gr. 1/10 (emetic).

2. *Sources of salicylic acid:* (1) Oil of wintergreen; (2) salicin; (3) synthetically, from sodium phenate and carbon dioxide.

3. The *source* of CARBO LIGNI is soft wood, charred without access of air. Its *therapeutic uses* are: For flatulence, as a mild laxative, deodorant, and absorbent.

4. (*a*) *Black wash* is made of calomel 5j to one pint of lime water. (*b*) *Dover's powder* is a mixture of ten parts of powdered opium, ten parts of ipecac, and eighty parts of sugar of milk.

5. *Six drugs containing tannic acid in large quantities:* Gambir, krameria, hæmatoxylon, hamamelis, geranium, and chimaphila.

6. *Three antiseptics for internal administration:* (1) *Urotropin:* colorless, odorless, crystalline; soluble in about equal parts of water; it inhibits the growth of microorganisms by reason of the formaldehyde which it yields up in the body in the urine; part of it is excreted unchanged and part as formaldehyde. (2) *Salol:* a white crystalline powder, very soluble in hot alcohol, but almost insoluble in water; it is decomposed into carbolic acid and salicylic acid. (3) *Naphthalene:* characteristic odor, aromatic taste, colorless, insoluble in water.

7. *Three Animal oils:* (1) Cod liver oil, from the liver of the cod; (2) Lard oil, from lard (from internal fat of the hog); (3) Neat's-foot oil, from the feet of neat cattle.

Three Vegetable oils: (1) Castor oil, from Ricinus communis; (2) croton oil, from croton tiglium; (3) olive oil, from ripe fruit of olea europœa.

8. *Tincture of the chloride of iron: Dose,* eight minims. *Physiological action:* astringent, hemostatic, gastrointestinal irritant, hæmatinic, and tonic.

CHEMISTRY.

1. There are eighty elements.

2. "A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism when under the influence of an electric current. Under the influence of these *physical forces* the iron suffers no change in composition, and, on cessation of the action of the inciting force, the iron returns to its original condition. But if the iron be heated in an atmosphere of oxygen, both the iron and a part of the oxygen disappear, and a new substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action*, causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action."—(Witthaus' *Manual of Chemistry.*)

3. The *metals* are all solid (except mercury), opaque, have metallic luster, are good conductors of heat and electricity, and will replace the hydrogen of acids to form salts.

Nonmetals do not have the above properties, some are gases, and their properties differ widely among the different elements.

4. Chlorides, bromides, and iodides are binary compounds of chlorine, bromine, and iodine, respectively. *Example:* Sodium chloride, NaCl; potassium bromide, KBr; potassium iodide, KI.

5. Allotropic form of oxygen is ozone. When pure, it is a dark blue liquid, almost opaque, it is a strong oxidizing agent; it oxidizes nearly all metals in the presence of moisture; it decolorizes organic pigments. *Symbol* is O_3.

6. OXYGEN. Molecular weight, 32; atomic volume is the atomic weight divided by the specific gravity; molecular volume, 22.4; density, 32.

7. In air there is 0.04 per cent. of carbon dioxide. The percentage dangerous to life depends upon the amount of oxygen present; probably 10 per cent. in the atmosphere would prove fatal.

8. Chloroform is a substitution product of methane. Three of the four hydrogen atoms of methane are replaced by three atoms of chlorine; hence the formula is $CHCl_3$, and the proper name would be Trichlormethane.

Chloroform can be obtained by heating chloral hydrate with an alkali:

$$C_2HCl_3(OH)_2 + KHO = CHCl_3 + HCOOK + H_2O$$

It is *prepared on a large scale* by the action of bleaching powder upon acetone:

$$2CO(CH_3)_2 + 6CaCl(OCl) = 2CHCl_3 + 2Ca(OH)_2 + Ca(CH.COO)_2 + 3CaCl_2.$$

HYGIENE.

1. *Six desirable factors in the location of a resort for consumptives:* (1) Pure and dry air, free from dust; (2) equable temperature; (3) protection from high winds; (4) dry soil; (5) high altitude; and (6) plenty of sunlight.

2. *Deleterious gases which accumulate in an improperly ventilated sleeping room:* Carbon dioxide, carbon monoxide, methane, sulphur dioxide, hydrogen sulphide, ammonium sulphide, ammonia, and organic vapors from decomposing animal matter.

3. *Nitrates* are generally due to the oxidation of organic matter of animal origin.

Nitrites generally indicate sewage contamination. The presence of nitrites should condemn the water; so should a marked amount of nitrates.

4. Organic heart disease, obesity, cirrhosis of kidney or liver, and arterio-sclerosis.

5. *The most efficient gaseous disinfectants* are: Formaldehyde, sulphur dioxide, and chlorine.

All apertures or crevices must be carefully closed, so that the gas used may remain as concentrated as possible.

6. Myopia is the most common abnormal condition of the eye in school children.

Habits tending to produce it are: Reading of fine or indistinct print, reading in poor illumination, improper positions in reading or writing, using the eyes when tired, and excessive study.

7. *Toxins* are harmful or poisonous products of bacteria.

Antitoxins are substances formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

8. "The methods used *in the production of antitoxins* were introduced by Behring, who found that by injecting susceptible animals with increasing amounts of extracellular toxin he produced in the blood-serum of the injected animal certain changes which made the serum capable of counteracting the same toxin when injected into other animals. . . . In practice, the bacilli are cultivated in bouillon. The cultures are freed from all living bacilli by filtration. The liquid filtrate contains the toxin. This filtrate is injected into healthy susceptible animals, in increasing doses. Usually the horse is used, since large quantities of blood can be drawn from this animal on account of its size, and, moreover, the horse is very susceptible. . . . Eventually enormous doses of toxin are given, and the animal acquires a high degree of immunity. The blood of the animal is withdrawn, taking care to avoid contamination, and the serum allowed to separate in the refrigerator. The serum of the blood is drawn off and constitutes the antitoxin."—(Williams' *Bacteriology.*)

8. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic microorganisms. Immunity may be either natural or acquired.

Natural immunity is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The conditions which give immunity are: (1) a previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Examples.—The rat is *naturally immune* to anthrax; the white mouse is *naturally immune* to infection with bacillus mallei. *Acquired immunity* is seen in the immunity from smallpox after vaccination, or after having suffered from an attack of the disease.

PATHOLOGY.

1. The phenomena of inflammation are dilatation of the arterioles, capillaries, and small veins. At first the blood current is quickened, then retardation occurs, and may progress to stasis and thrombosis. During this time exudation of plasma and white corpuscles from the small veins, and perhaps the capillaries, is going on. The fate of the white cell may be either to break up and set free prothrombin, or to act as food for connective tissue cells, or to act as a phagocyte and be transformed into a pus corpuscle. Red corpuscles may be exuded and broken up, setting free their coloring matter. The prothrombin of the white cells unites with the calcium chloride of the plasma, and forms thrombin, or fibrin ferment, which acts upon the fibrinogen of plasma to form fibrin.

The tissues are thus invaded with numbers of leucocytes. In bacterial inflammation a varying portion of the tissues is killed by the toxins produced, and is either replaced by a mass of small round cells, or liquefied into pus. In the latter case it is surrounded by a ring of small round cells. The connective tissue cells absorb the leucoeytes, and new vessels are formed, thus constituting repair. In nonbacterial inflammation, exudation may separate layers of cells to a large extent and form blebs. In chronic inflammation the formation of new fibrous tissue is the chief part of the process.—(From *Aids to Surgery.*)

2. *The joint changes in arthritis deformans* are: Proliferation of the cartilage cells, the edges of the cartilage become fibrillated and wear away; the underlying bone becomes hard and polished, and later atrophies in parts, part of the bone becomes absorbed; ossification may also occur, with locking of the joint; the synovial membrane may either atrophy or hypertrophy.

3. *In the typhoid ulcer:* (1) The main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation.

In tubercular ulcer: (1) The long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined.

4. *The conditions which predispose to cerebral hemorrhage* are: Advanced age, rheumatism, gout, syphilis, alcoholic excesses, Bright's disease, prolonged muscular exertion, chronic lead poisoning, severe physical or mental excitement.

5. *Spleen enlargement may be found in:* Typhoid fever, malaria, leukemia, pernicious anemia, cirrhosis of liver, and many of the infectious diseases (diphtheria, scarlet fever, erysipelas, pneumonia) and septic processes (septicemia and pyemia)

6. *Hematuria* is blood in the urine.

Hemoglobinuria is blood pigment in the urine.

In *hematuria* a microscopical examination will show numerous red blood corpuscles in the urine; in the other condition red cells are either absent or are very scanty.

The *principal causes of hematuria* are: (1) Conditions in which the blood is affected, as in the infectious diseases, in scurvy, pernicious anemia, and purpura; (2) traumatism or inflammations in any part of the urinary tract; (3) congestion of the kidneys secondary to disease of the lungs, heart, or liver.

The *principal causes of hemoglobinuria* are: Poisons, such as arsenic, potassium chlorate, carbolic acid, carbon monoxide; jaundice, malaria, syphilis, Raynaud's disease, scurvy, purpura.

7. In *acute anterior poliomyelitis:* Congestion and then destruction of the ganglion cells in the anterior horns of the spinal cord; there is an infiltration of leucocytes; and an overgrowth of connective tissue replaces the cells in the anterior horns. The fibers of the anterior roots show degeneration; the posterior roots are not affected.

8. *Inflammatory conditions which may result in enlargement of the lymphatic gland:* Tonsillitis, gonorrhea, chancroid, syphilis, septic infections.

OBSTETRICS.

1. The ovum when fully developed is a single cell, spherical, about 1/125 inch in diameter; it is composed of a yolk, with nucleus, nucleolus, and two enveloping membranes.

2. The *liquor amnii* is the fluid contained in the amniotic sac; it is alkaline in reaction, has a specific gravity of about 1.001 to 1.008, its quantity is variable, but is generally about two pints. It consists chiefly of water, but contains small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its source is unsettled.

Functions: (*a*) *During Pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus.

(*b*) *During Labor:* It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

5. *Causes of vomiting in pregnancy* are: (1) Reflex disturbance, due to rapid growth and excessive distention of the uterus; (2) disease or displacement of uterus, tubes, and ovaries; (3) disease of pelvis or gastrointestinal tract; (4) excessive sexual intercourse; (5) renal disease or disturbance.

6. *Conditions warranting the induction of premature labor:* (1) Certain pelvic deformities, (2) placenta prævia, (3) pernicious anemia, (4) toxemia of pregnancy, (5) habitual death of the fetus toward the end of pregnancy, (6) hydatidiform mole, (7) habitually large fetal head.

The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerin, water, or some other fluid.

7. The *absolute indications of cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death.

8. *Conditions which retard or obstruct labor:* Rigidity, edema, atresia, or displacement of the os or cervix; fibrous bands, or atresia of vagina; persistent hymen; unyielding perineum; tumors; distended bladder or rectum; hernia; edema of labia; pelvic deformities; malpositions or malpresentations of the fetus; prolapse of limbs; short cord; large fetus; dead fetus; twins or monstrosities; uterine inertia; rupture of uterus

SURGERY.

1. *The indications for ligation of an artery in its continuity* are: To check hemorrhage, to promote the cure of an aneurysm, to diminish the rate of growth of a tumor, to cause atrophy of an organ by diminishing its blood supply, as a preliminary to removing some vascular structure (such as the tongue).

2. *Division of the radial nerve* would be followed by: Loss or impairment of sensation in the dorsal aspect of

thumb, index finger, and radial side of middle finger as far as the second phalanx.

3. *The possible obstacles to reduction of a dislocation* are: Torn capsule embracing the neck of the bone, muscular contraction, interlocking of bony points; inflammatory swelling of the soft parts, and tendons or muscles catching around the neck of the displaced bone.

4. *Principles of treatment in compound dislocations:* Open up the wound if there is any chance of its being infected, remove destroyed tissue, irrigate thoroughly, reduce the dislocation, pack with gauze, drain, and immobilize.

5. *Delayed union in fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

Treatment: "When delayed union exists, seek and remove cause treating constitutionally if required, and thoroughly immobilizing the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussion over the fracture, and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodine or firing it has been employed. If the case be very long delayed, forcibly separate the fragments and put up in plaster as a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places." (Da Costa.)

6. *Wounds are classified* as: (1) Contused and open. (2) Open wounds may be: Incised, lacerated, contused, punctured, gunshot, or poisoned; also penetrating and perforating. (3) Aseptic and septic.

7. *Symptoms of cholecystitis:* Pain and tenderness in region of gall-bladder; fever, rapid pulse, vomiting, rigid abdominal muscles, jaundice may be present.

8. A *tumor* is a pathological new growth which tends to persist independently of the tissues in which it is found, and which serves no physiological purpose.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct. 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 3
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 9
Delaware	J. H. Wilson, Dover	Dover	Dec. 14
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Oct. 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 10
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 12
Idaho*	W. F. Howard, Pocatello	Boise	Oct. —
Illinois	J. A. Egan, Springfield	Chicago	Oct. 20
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 11
Iowa	Louis A. Thomas, Des Moines	DesMoines	Sept. —
Kansas	F. P. Hatfield, Olathe	Kansas City	Oct. 12
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta	Nov. —
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 14

Wisconsin	J. V. Stevens, Jefferson	Milwaukee	Jan. 11
Wyoming	S. B. Miller, Laramie	Laramie	Oct. 20

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular state.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of August 21, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	565	137
Diphtheria	141	10
Measles	149	12
Scarlet Fever	68	4
Smallpox	—	—
Varicella	6	—
Typhoid Fever	74	15
Whooping Cough	25	8
Cerebrospinal Meningitis	8	11
Malarial Fever	.	..
Totals	1,036	197

Histological Alterations of the Organs in Croup.—Antonio Ghiotti has examined the internal organs in ten cases dying from diphtheria. He finds hepatization with emphysema in the lungs, peribronchitis in one case, false membrane in the bronchi in two cases, hyaline degeneration of the walls of the vessels, and dry pleurisy in three cases. In the liver fatty degeneration of the periphery of the acini, with cirrhosis, hyaline degeneration of the vessel walls, and hypertrophy of the intima of the hepatic arteries. In the spleen a septic condition, with degeneration of the vessels and hemorrhage into the spleen substance. In the kidneys inflammatory reaction of hemorrhagic type. Endocarditis and pericarditis were very evident.—*Giornale Internazionale delle Scienze Mediche.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending August 20, 1909:

SMALLPOX—UNITED STATES.

ADDRESS ON CANCER IN MAN AND ANIMALS.*

BY E. F. BASHFORD, M.D.,

LONDON,

DIRECTOR IMPERIAL CANCER RESEARCH FUND.

A COMPLETE change has been effected in many aspects of the cancer problem during the past seven years, and I propose to give you some account of the share the Imperial Cancer Research has had in effecting it. The extent of the ground I shall have to cover must be my excuse for the imperfect references I shall make to the valuable work of investigators in other centers of active investigation of cancer.† Reasoning can no longer commence with the postulate that the disease is limited to white man, and in consequence of his transmitting it to races living under the circumstances peculiar to his particular form of civilization, and to his domesticated animals. On the contrary, the liability to cancer of all races of mankind, and of all vertebrates, even when living in natural conditions, has been established as a fact from which all attempts to explain the disease must start. Whilst all claims to have transferred cancer experimentally previous to 1900 had either broken down before the criticism that the lesions adduced to substantiate the claim were not the lesions of cancer, or had been received with scepticism from lack of confirmation, as in the case of Hanau and Morau, the experimetal reproduction, at will, of the lesions of carcinoma and sarcoma has to-day become a matter of mere laboratory routine. I shall attempt to show you that these two achievements have established the investigation of cancer upon a sound comparative biological and experimental basis; further, that they have done away with the stagnation of thought and with the pessimism pervading the minds of the scientific public at the close of the nineteenth century. Under their auspices rapid progress has been made in defining more narrowly both the nature of the disease, and the direction in which its ultimate explanation will be found.

Although the immediate consequence has been the possibility of conducting a multiplicity of highly specialized investigations, and although no revolutionary generalization on the etiology, or on the prevention and treatment of cancer is yet possible, still that steady advance in knowledge which the successful application of the experimental method has always foreshadowed in other paths of human endeavor, may be anticipated also in the case of cancer. So much is certain. Whether a chance observation appreciated and followed up with genius, may lead to a sudden and unexpected relief of human anxiety and suffering, it is impossible to foresee, but the ever increasing army of investigators augurs well for so important a chance opportunity not being missed, should it present itself.

Incidence of Cancer in Vertebrates.—The experimental studies of the Imperial Cancer Research differ from similar investigations in that they have been co-ordinated from their inception in September, 1902, with the study of the natural incidence of the disease in all races of mankind and throughout the vertebrate kingdom. I illustrate the occurrence of congenital malignant new growths in savage races of man, remote from the influences of civilization, by a portrait of a mother and child from West Africa, which child died from a glio-sarcoma of the orbit. Where the disease was said to be rare, *e. g.* in Japan, excellent statistics exist of which Europeans were previously ignorant, showing over 25,000 deaths from cancer annually, and, therefore, proving cancer among the Japanese to be probably as frequent as among Englishmen or Germans. Taking another example, certain forms of cancer very common in London hospitals, *e. g.* carcinoma of the lip, tongue, cheek, breast, uterus, are probably not less common in hospitals throughout Hindustan.

When every possible weight is given to the reservations with which comparisons may be made between hospital figures obtained in London and in Hindustan, the figures from Indian hospitals present a very striking result. While cancer of the testis and penis is nearly ten times as frequent as in English hospitals, cancer of the lip, tongue, cheek, etc., contributes nearly the same proportion. Among females the same correspondence is found, cancer of the uterus being slightly more frequent than in English hospitals, and cancer of the breast equalling more than three-fifths of the English hospital figures. Cancer of the lip, tongue, cheek, etc., is, on the contrary, more than six times as frequent in female Indian hospital patients as in the corresponding English group. The slight differences between the frequency of cancer of the breast and uterus revealed by comparing the figures for English and Indian hospitals, make it at least possible that the mortality in India from cancer of these organs may be not markedly different from that in England. Exceptional opportunities are afforded in India for the study of the incidence of cancer in vegetarians and flesh-eaters, since the diet is strictly ordained by the customs of the different native castes. In India the disease occurs irrespective of vegetarian or meat diet just as it occurs in herbivorous and carnivorous mammals. In Egypt, also, cancer is far from rare

*Address delivered before a general meeting of the Sixteenth International Medical Congress, Budapest, August 29-September 4, 1909.

†Full references to the work of others will be found in the publications of the Imperial Cancer Research, *e. g.* in the Third Scientific Report, 1908. Taylor & Francis, Red Lion Court, Fleet street, London, E. C.

In the case of most aboriginal races there are insurmountable difficulties in the way of even thus roughly estimating the frequency of cancer among them. Therefore, it is idle to affirm or to deny that it may be more common in some races than in others. The fact of moment is that the disease occurs in savage races, as I illustrate, for a carcinoma mammae in a native woman of the Sudan, and for an epithelioma of the jaw in a Dinka of the White Nile, as well as for an osteochondro-sarcoma in a native of Northern Nigeria. Therefore, foci from which the disease could spread are present in the most uncivilized of races; nevertheless, no indication of the endemic or epidemic occurrence of malignant new growths in savage races has been found, nor has it been possible to establish any relation between the frequency with which cancer is recorded in aboriginal races and the degree of exposure to contact with Europeans. There is nothing comparable to the aggravated and fatal epidemics following the introduction of infective disease into such races.

Carcinoma and sarcoma occur not only throughout the human race, but also throughout the other vertebrates. The similarities of the lesions characteristic of malignant new growths are well demonstrated by comparing the series of figures I show you of carcinomata of the skin in man, other mammals, bird, frog, fish, *i. e.* throughout the vertebrates down to marine fish living in a state of nature. Malignant new growths occur not only on the surface of the body but also in the internal organs of the lower vertebrates, as illustrated by slides of an adenocarcinoma of the kidney in a frog, an adenocarcinoma of the liver in a trout, and an adenocarcinoma from the abdomen of a marine fish, viz., a gurnard. The trout is peculiarly liable, under certain conditions, to a general hyperplasia of the thyroid. We have records of 2,000 cases, in many of which true carcinomata have supervened, such as shown on the slide.

Our earliest contributions to the experimental study of cancer were made with the knowledge that the disease occurred throughout the vertebrates. The negative criticism and active opposition accorded to the results of Jensen, Borrel and ourselves from 1903 onwards, and also later to those of Ehrlich and Apolant, by pathologists of recognized authority in England and Germany appeared to us both inexplicable and unjustified. In the light of our comparative experience it would have been strange indeed if the mouse had proved to be exempt from cancer. Orth has recently written "there occur in mice tumors which, although not identical in every respect with human carcinomata, nevertheless exhibit so many points of similarity with the latter, that it appears correct to designate them as carcinomata of the mouse, and to apply the observations made on them to human pathology with the precaution necessary in all experimental and comparative pathological investigations." This statement by Orth, conceding all we have ever contended for, marks the end of any serious opposition to the experimental study of cancer.

It has been too often wrongly asserted that the mouse suffers only from carcinoma of the mamma. I illustrate the liability of the mouse to other forms of malignant new growths by a selection of slides from specimens in our collection, of carcinoma of the stomach, small intestine, pancreas, ovary, liver, lung, skin, sebaceous gland, preputial glands, also of sarcoma of the kidney, osteo-chondro-sarcoma, melanoma, lymphosarcoma. Borrel and Haaland have described squamous celled carcinoma of the floor of the mouth, and lymphosarcoma; Haaland has described squamous celled carcinoma of the vulva, and adenocarcinoma of the lung, as well as chondrosarcoma of the vertebral column; Ehrlich has described a chondroma probably of congenital origin; carcinoma of the uterus has been recorded from Buffalo; Tyzzer has described papillary cystadenoma of the lung, cystadenoma of the kidney, and lymphosarcoma; Jobling has recorded spindle-cell sarcoma on the chest wall (? mamma) and papillary cystadenoma of the ovary. The great liability of the female mouse to cancer of the mamma is merely an idiosyncrasy shared with the human female and female dog.

I show you some histological pictures of typical adenocarcinoma and alveolar carcinoma of the mamma of the mouse, and exhibit several figures of mice showing primary growths and their metastases in the lungs and lymph glands. The clinical course, the results of surgical or other treatment, the pathological findings and relation to general metabolism have been carefully recorded in our laboratory for over 300 mice suffering from malignant new growths of the mamma. On a lantern slide has been grouped the clinical course of a few cases of carcinoma of the mamma, illustrating well their liability to recur after complete surgical removal has been attempted, and the fatal termination in consequence of dissemination or terminal cachexia. The observations agree with medical, surgical, and pathological experience in the human subject, and demonstrate how secure is the basis they afford for attempts to apply the results obtained by studying the disease in mice to the disease as it occurs in man. The main danger of the disease lies in the difficulty of diagnosing it in a stage permitting complete removal, and still more in anticipating dissemination throughout the body. The prolonged relief surgery can give is shown by the absence of recurrence or of metastases for months after removal of the primary growth. That the period of relief may equal one-third of the total life of the mouse justifies, and experimentally demonstrates the value of the surgical treatment of the disease in man, so long as there remains no alternative to it. Convenience and questions of expense have led to the experimental investigation of cancer being developed on the basis of experience gained, for the most part, on mice, although the rat, dog, and other larger mammals have been employed by us to a less extent.

Experimental Reproduction of the Lesions of Cancer.—For two years it looked as if the experimental study of cancer was going to break down once more in face of the criticism that the lesions of the disease, as it occurs naturally, were not reproduced experimentally. However, the weaknesses in the chain of evidence were due merely to the technique of experimentation not having been properly mastered, and early in 1905 we were able to demonstrate that a mammary carcinoma when inoculated into normal animals produced metastases in the lungs, where, rupturing the pulmonary artery, they infiltrated the lung tissue and broke into the bronchi; we also demonstrated invasion of the intestinal wall from the peritoneum by way of the lymphatics, and pointed to the close resemblance the resulting lesion showed to a spontaneous carcinoma of the intestine of a mouse. We concluded that there was complete identity in all the phenomena due to growth, between the sporadic tumors of man and animals, and also that the

phenomena were perfectly reproduced in artificially propagated tumors of the mouse. In short, all the clinical and pathological features of cancer including the terminal cachexia were the consequences of cell proliferation confined in the first place to a few cells in a very circumscribed area. At the same time Haaland working with Borrel in the Institut Pasteur independently showed the frequent occurrence of microscopical metastases in the pulmonary artery in the case of a mammary carcinoma, and at a later date he also demonstrated with great completeness the phenomena of dissemination in the case of sarcoma. With the lapse of time the material accumulated in our laboratory has made the demonstration of the reproduction of the anatomical lesions and clinical features more and more perfect, and to-day it lacks nothing in completeness either from carcinoma or sarcoma, as the slides I show of the experimental reproduction of infiltrative and expansive growth, of pulmonary and lymphatic metastases, as well as the close correspondence between a spontaneous carcinoma of the intestine of a mouse, and the lesions produced experimentally in the intestine amply demonstrate. Dissemination may be so widespread that metastases are present in the lungs, kidneys, liver, and intestine, etc., of one single animal, as shown on another slide. These lesions have resulted, in every case, from the growth of a minute particle of cancer tissue introduced into a normal mouse by means of a hypodermic needle. Jensen's great service in advancing the knowledge of cancer consists in the fact that, unlike his predecessors—Morau and Hanau who to-day we recognize as having successfully transferred cancer from one animal to another of the same species—he did not restrict himself to producing at the site of inoculation a tumor with the histological structure of the original growth. Jensen proved in 1903 by carefully following the processes at the site of inoculation, step by step, that the new tumor was due to the continued growth of the cells of the original or parent tumor, parts of which he had introduced. The fact that metastases did not occur in his experiments detracts nothing from their value. Jensen's work was followed almost immediately by that of Borrel, and also by that of Murray and myself in the same year. We confirmed Jensen's observations and extended them to a large number of other malignant new growths of mice. One of the most instructive being a squamous-celled carcinoma, of which I show slides of preparations made from the first and from the ninth subtransplantation. The typical structure of the skin is beautifully reproduced in the ninth subtransplantation, as is shown under both low and high magnification.

After some preliminary controversy it is now agreed that infection plays no part in the experimental transference of cancer, which is a true transplantation of living cells. The introduction of a particle of living tissue by means of a hypodermic needle does not reproduce the anatomical relations obtaining when normal cells become cancerous, and there would have been nothing to cause surprise had the cancer cells continued to grow only at the site of inoculation; indeed, notwithstanding the demonstration already given in 1905 and alluded to above, so little surprise was aroused in the minds of some experimenters at their failure to reproduce the lesions of dissemination, that Ehrlich in 1906, in setting up the doctrine of atrepsy, relied to a large extent on the assumption that their absence was of fundamental moment, and due to the tumor at the site of inoculation so withdrawing the food supply as to prevent its off-shoots from establishing themselves in distant organs. The absence of metastases is due, for the most part, to technical details in the procedure of inoculation and to the duration of the growth of the resulting tumor. The reproduction of the lesions has become in our experience, a commonplace of laboratory routine. A survey of the facts on the experimental reproduction of the lesions of cancer affords a demonstration of the adequacy of Ribbert's view, that all the lesions of the disease, as it is exhibited in man, may be the consequence of the continued growth of cells which primarily were confined within a small circumscribed area.

The "Age-Incidence" of Cancer and the Experimental Distinctions Between Young and Old Mice.—The investigations of the Imperial Cancer Research have settled once and for all that cancer is a disease common to mankind throughout the world, and to vertebrates. The illustrations I have shown you demonstrate clearly how closely the primary lesions of the disease resemble one another, even when occurring in animals so remote as man and fish. There is, however, another common and even more striking feature of the disease. Its peculiar association with certain periods of life in man, known as the "age-incidence" of cancer, reveals a law applicable to all vertebrates. A demonstration of its validity for the mouse is given by the following table showing the liability of the female mouse to carcinoma of the mamma at difference age-periods:

Age	6–9 Months	12 Months	15 Months	18 Months	21 Months	24 Months and Over
Total	135	110	94	21	6	..
Cancer	3	4	7	3	2	.....
Per cent	2.2	3.5	7.4	14.2	33.3	.....

The progressive increase shown in the table presents a remarkable parallel with the age-incidence of cancer of the mamma in the human female shown in the next table, and also adds a statistical confirmation to the results of our comparative histological and biological studies, which have shown the close parallel, amounting in many particulars to complete identity, between malignant new growths in man and other vertebrates. The above table demonstrates that the law of the age-incidence of the disease holds for the shortest lived mammals as it holds for man. Since the less perfect data for other vertebrates are in complete accord with the facts established for mankind and for mice, the general application of the law of age-incidence is probable and, therefore, any explanation of the etiology of cancer must accord with the circumstance that when considered *statistically* cancer is a function of age, and when considered *biologically* a function of senescence. The main condition for discovering a considerable number of cases in civilized and in savage man, in mammals, and in vertebrates generally, is the examination of a sufficiently large number of adult and aged individuals* The law of the age-incidence of cancer is of fundamental etiological and general biological importance. It applies both collectively and indi-

Many aged persons escape cancer, which it must be distinctly pointed out is not caused by old age, and senescence whether constitutional or confined to circumscribed areas of tissues is only an endogenous predisposing factor.

At the commencement of the experimental study of cancer it was quite natural that old animals should be selected for inoculation purposes. We speedily found, however, that they are much less suited for the transplantation and growth of cancer than are young animals, as the following two charts show. The first chart (Fig. 2) illustrates the

growth of our tumor "63" in three groups of mice, young, middle-aged, and old. You will notice a progressive diminution in the number of tumors

developing as well as in their respective rates of growth. Tumor "63" shows itself less susceptible to differences due to age than are other tumors, as illustrated in the second chart (Fig. 3) for tumor "32," where you will notice the same progressive diminution in the number of tumors and in their rates of growth, according as inoculation was made into young, middle-aged, or old mice. Indeed, progressive growth did not take place in a single old mouse. At the end of four weeks all the old mice had cured themselves of the tumors "32." Such observations enabled Murray and myself to analyze some of the relations obtaining between the origin and the growth of cancer. In the first place they agree with the more rapid growth observed in the human subject, when cancer develops in young people. They also demonstrate that, while senescence is intimately associated with the inception of cancer, it is not necessary for its continued growth, and, therefore, the origin and the growth of cancer may be considered separately. I shall have to revert later to the respective parts played by the localized tissue changes and the constitutional conditions associated with the natural development and the growth of cancer. What is studied in the transplantation of cancer is the ability of tumor cells to establish themselves in new hosts and their powers of continued growth. In order to obtain uniform results great care must be taken to secure animals of uniform age. Old age of itself suffices to render mice absolutely resistant to the inoculation of cancer. As the second chart shows with clearness, the fact that the cells are able to establish themselves does not necessarily mean that they will be able to continue to proliferate, and, later on, I shall demonstrate to you that growth is frequently terminated by the immunity which the tumors induce against themselves. The difference between inoculating tumors into young and into old mice is of great technical moment in the interpretation of experiments on immunity, as is evident from the charts I have just exhibited. No conclusion can be drawn from experiments bearing on the artificial induction of immunity, or resistance, to the inoculation and growth of cancer, if this factor alone, or together with others to be mentioned later on, has been neglected or not adequately allowed for. This is, unfortunately, the case in all experiments except those conducted in our laboratory. I shall have to refer to this fact again when discussing whether the resistance which can be induced by tumor-tissue and by normal tissue is specific or general in its nature.

The Alleged Increase of Cancer.—It follows from what has been said above on the statistical importance of the age-incidence of cancer, that very full attention must be given to the relative numbers of the population in different age periods, whenever any attempt is made to appraise the frequency of cancer. The problem of the relative frequency of cancer in this or that population and area, overlaps the much discussed question of its alleged increase. Savage races are unsuited for the study of both these problems and also for the investigation of the relative liability of different sites of the body. By the time the natives of Central Africa have so organized their communal life that reliable vital statistics are forthcoming, the conditions of life among them will no longer be what they are today, and no doubt they will be interested in what to them may be a new problem, "the alleged increase of cancer." We have seen this stage reached at successive intervals in different countries with the progressive improvement of their national statistics, and, since the work of the Imperial Cancer Research was started, Europeans have passed from the belief that cancer was rare or did not occur, *e. g.* in Japan, India, and Egypt, to the minor questions of its relative frequency, or its real or apparent increase in those countries.

It may be added that, when our investigations were commenced and the determination come to in September, 1902, to study cancer in animals, doubts were expressed by some as to whether the difficulty of finding a sufficient number of cases would not prove insurmountable. The large number of cases of cancer, over 1,000, which have been observed in mice, by various investigators during the past six years, does not mean an increased liability of mice to cancer, but simply that it has been looked for with care in sufficiently large numbers of adult and aged animals, and found. The increase in the number of cases recorded throughout the vertebrates has the same significance.

The number of deaths assigned to cancer has increased from year to year in practically all countries. This increase is made to appear most alarming when it is taken up as a national problem, *e.g.* in England, Germany, or the United States, without due regard to the universality of the phenomenon. When due regard is paid to its universality in man and in animals, to the varying value of the data used for statistical purposes in different countries, and in the same country at different times, as well as to the varying accuracy of the statistical methods employed, I very much question if those persons who have made exaggerated statements to the effect that the recorded increase of cancer represents a true and relatively increased liability to it, have any excuse whatsoever for enhancing the reasonable anxiety of the lay public.

Without digressing into a discussion of the statistics of cancer, I would point out that the number of deaths assigned to it as a cause of death increases from one country to another parallel with the increasing accuracy of the vital statistics of the several countries, as the following table from the Report of the Registrar-General shows:

CANCER—DEATH RATES PER 1,000 PERSONS LIVING 1881–1907

COUNTRIES (Arranged in Order of rates in 1901–1905)	QUINQUENNIAL PERIODS					YEARS

*Four years †Three years.

The recognizable sources of fallacy in the data on which the above table is compiled, and in the institution of comparisons between the cancer death-rates in different countries, carry more weight with accurate statisticians than the differences ex-

isting between the figures for different countries. The differences between different countries, which the table shows, reproduce also the various stages through which the statistics of single countries have passed in the course of their development, and the same reasoning makes obvious their dubious value as evidence that the differences in the statistics of the same country at different times reveal real differences. Passing over statistical method, I would point out that out of 10,532 cases of cancer treated in hospital, *i. e.* under the most favorable circumstances for diagnosis, 1801 were not diagnosed as cancer from clinical evidence alone. Out of 9488 cases treated as cancer, 757 were not suffering from the disease. The following table illustrates the relative proportions in which the disease was diagnosed in different sites of the body according to their accessibility to complete physical examination:

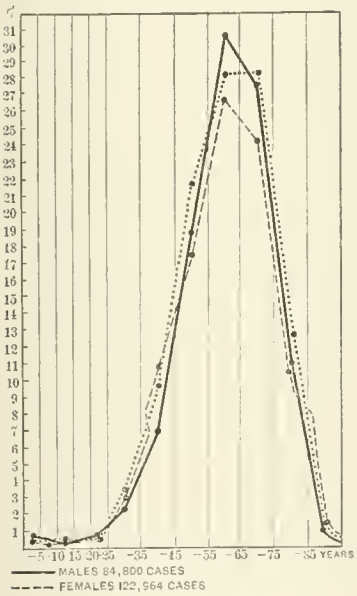
Analysis of the Cases of New Growths Reported by the Hospital Authorities. 1904–9 All Ages. Microscopical Examination has been Made in all Cases.

	Malignant New Growths.		
	Correctly Diagnosed	Not Diagnosed	Wrongly Diagnosed as Cancer
Accessible	5854	567	438
Inaccessible	1555	945	159
Intermediate	1322	289	160
Total	8731	1801	757
Accessible	91.1%	8.9%	
Inaccessible	62.2%	37.8%	
Intermediate	82.0%	18.0%	
Accessible	93.0%		7.0%
Inaccessible	90.7%		9.3%
Intermediate	89.2%		10.8%

The errors of diagnosis in general practice are probably not less than in hospitals, although, of course, no direct comparison is possible between hospital patients and the general population. I need not enlarge upon the possibilities of improving the diagnosis of cancer in savage races and in animals, but it may be well to point out that the opportunities for their reaching cancer-ages in large numbers are absent in many instances. The greater frequency of cancer in domesticated as compared with wild animals, appears to be due, as we pointed out in 1903, not to contact with man, but to the fact that man so provides for, and protects them, that higher proportions live long enough to attain to their respective cancer ages.

In recent years the attempt has been made to advance the statistical study of cancer, not by enumerating the numbers of those *dead* from it, but by making a census of persons *suffering* from it. The difficulties are greater in telling if a person is suffering from cancer than in determining if he died of it. The method is as fallacious statistically as is reliance on hospital statistics in order to adduce evidence of the increase of cancer. The collection of the clinical and pathological data from hospitals, given in the above table, has demonstrated that the taking of a census of cancer patients in the general population is an absolutely worthless tabulation of data vitiated by an exaggeration of all the fallacies inseparable from data of mortality. An improvement in the value of the statistical investigation of cancer is to be expected only from an improvement in mortality statistics as a whole, *i. e.* by an increase in the accuracy of all the data on which vital statistics are necessarily based. The necessity for greater completeness, uniformity, and accuracy of the data of mortality, and of those relating to the age-constitutions of populations, applies still more urgently if comparisons are to be made between the statistics of cancer of different countries. Comparisons between different countries will be made profitable only by an all-round raising of the standards of accuracy and completeness of vital and mortality statistics. For these and other reasons a cancer-census has not been made in England. Where one has been made, *e. g.* in Germany, Holland, Hungary, and Spain, it has left all the problems of cancer just as they were. For these reasons we also consider the attempt to compile uniform international cancer statistics a counsel of perfection, and a utopian scheme diverting both energy and money from other and more profitable lines of investigation.

There is no doubt that an absolute increase of the number of cases of cancer *recorded* from year to year is taking place not only in practically all races of mankind, but also in vertebrate animals. Nevertheless, to alarm the public by proclaiming this as "an increase of cancer" in the sense that there is an increase disproportionate to the numbers and age-constitution of the populations examined is pure sophistry. Much of this increase can be referred with certainty to the larger number of individuals attaining to the "cancer age;" another considerable proportion can be referred with equal certainty to greater care in searching for the disease, as demonstrated for many native races and for animals. The universal endeavor to improve vital statistics in all countries is also in part responsible. Reviewing the whole circumstances, one must concede that these factors have been potent ever since statistics of any kind were available, and, although it is impossible to deny that a relatively greater proportion of the population may die of cancer than previously was the case, nevertheless, a real increase cannot be proved, and what has been made a cause of public anxiety appears to have little or no existence in fact.



5 10 15 20-25 -35 -45 -55 -65 -75 -85 YEARS

Fig. 4.—Percentage distribution of deaths from malignant disease in England and Wales, 1901-1907.

The Incidence of Cancer on Different Parts of the Body.—In considering the etiology of cancer regard must be paid to the sites of predilection. According to the national mortality statistics of England and Wales, among males the organ most frequently invaded is the stomach; it is the seat of the disease in nearly 22 per cent. of the fatal cases, the liver and gall bladder are invaded in nearly 13 per cent. of the whole, the rectum in 10 per cent., and the intestine in 8 per cent. Taken together the parts here specified are attacked in more than two-fifths of the total cases, recorded in

the national mortality statistics. Among females the generative and mammary organs are affected in more than two-fifths of the total fatal cases: while a further two-fifths are contributed by the stomach, liver, intestines, and rectum, taken together. It is well known that cancer is more fatal to women than to men, and that this fact is accounted for by the greater frequency with which the generative and mammary organs are attacked in women, is shown by the accompanying two curves (Figs. 4 and 5) illustrating the general similarity, but also the important differences, which obtain between the general population and a hospital population. In the latter all cases have been examined microscopically. One important difference is of interest, the maximum for the fatal cases in the general population occurs between 55 and 65, or ten years later than in hospital patients. This difference is partly accounted for by the duration of the disease from the time it is observed till the fatal issue, but is also to some extent an expression of the beneficial effects of surgical treatment by postponing death till the patients fall under the next decennial age-period. I need not do more than allude to sources of fallacy if any attempt be made to magnify the importance of the differing maxima.

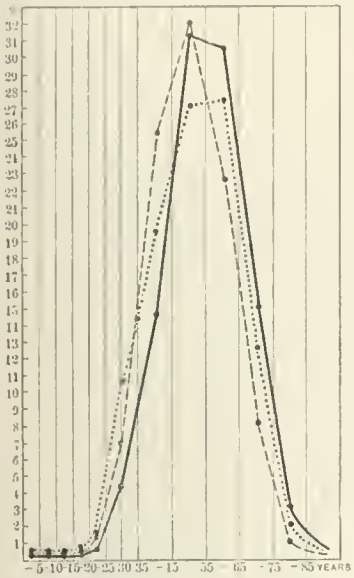

Fig. 5.—Percentage distribution of cases of cancer in hospitals, for comparison with Fig. 4.

In England and Wales in the seven years ending with 1907 the recorded deaths of males from malignant disease other than that of the generative and mammary organs were equal to a rate of 730 per million; whilst the deaths of females with the same reservation did not exceed 594 per million, the total deaths from all forms of cancer being 84,300 males, and 122,964 females. Therefore, when other individual organs are considered, there is an opposite contrast between the two sexes, *e. g.* cancer of the lip, tongue, œsophagus, stomach, and rectum, is much more common in men than in women, but in women cancer of the gall bladder and liver is perhaps more common than in men. On the whole, the liability of males, both generally and for individual organs—excluding the generative and mammary organs—is greater than that of females, and it appears possible that the difference is due not merely, if at all, to constitutional conditions determined by sex, but also to local circumstances peculiar to the organ attacked, perhaps by the customs of the two sexes, in the same way as the difference in the customs of women in India and in Europe determine their respective liability to and exemption from carcinoma of the mouth. I shall have to refer later to the enhanced importance thrown by comparative and experimental studies on the association of cancer of the skin with chronic iritation, and I may allude here to its possible importance also in connection with cancer of the alimentary tract. The difference in the proportionate incidence of cancer on the upper and lower halves of the alimentary canal in males and females, respectively, is brought out diagrammatically by curves for the population generally (Fig. 6), and for hospital patients (Fig. 7). The details lacking for different sites for the general population are available for hospital patients and may be cautiously employed to elucidate the mortality statistics. The curves of liability for the two sexes cross at the stomach in both, so that for males a higher proportion of cases of cancer of the alimentary canal occur above the stomach than below it, the opposite relation obtaining for the female sex. This relationship may be brought into connection with the different habits of the two sexes in consequence of which the upper part of the alimentary canal is more exposed to chronic irritants in males, and the lower part in females.

The predilection for some sites rather than for others in mankind, and even the preponderance of certain forms of cancer in a single organ, *e. g.* scirrhus carcinoma of the breast in the human female, must be considered from another standpoint than that of chronic irritation. These sites of predilection reveal the existence of endogenous factors associated with cancer, when considered in the light of comparative investigation. In surveying the incidence of cancer in the vertebrate kingdom, one has been struck by the fact that certain forms appear to preponderate in different classes, *e. g.* carcinoma of the thyroid in the trout. In the mammalia some species are very liable to forms of cancer of the mamma from which others, even nearly allied, are relatively or altogether exempt. Cancer of the mamma is extremely rare in the cow, common in the human female, the dog, and the mouse. In the animals liable to cancer of the mamma, the disease exhibits specific characters in the relation between the epithelial and connective tissues, *e. g.* scirrhus in the human female, delicate

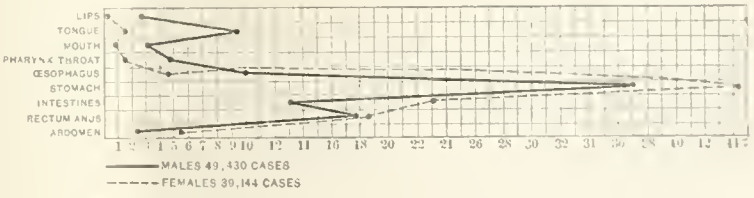

Fig. 6.—Deaths from malignant diseases of the alimentary canal (England and Wales, 1901-1907), classified according to sex and part affected.

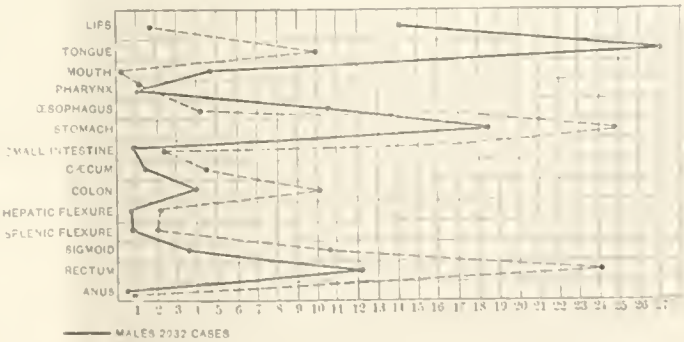

Fig. 7.—Incidence of carcinoma of the alimentary canal (hospital cases) classified according to sex and part affected.

stroma and great tendency to dilated blood-sinuses and to hemorrhages in the mouse, in the dog tendency of the connective tissue scaffolding to the formation of cartilage and bone, in the rat to the formation of dense sclerotic tissue as in the human female. When fuller facts are available, it will probably be found that the sites of election do really vary from one class or even nearly related species of animal to another. Since external conditions, *e. g.* chronic irritation, and modes of life cannot be made entirely responsible for the differences they can be referred with some certainty to innate peculiarities of the several different mammalian organisms, predisposing certain organs to, or exempting them from cancer, and determining even the type of growth preponderating in an organ, *e.g.* the mamma. It seems difficult to escape concluding that these differences justify the assumption that distinctive interrelations exist between malignant new growths of the same organ in different species, *e. g.* the mamma, and the entire organism. We are thus brought face to face with local and constitutional conditions associated with cancer, and when we come to prepare differences in the incident of cancer in individuals of the same variety of a species, we are tempted to assume an innate, or an acquired local or constitutional predisposition in one case and exemption in another.

Chronic Irritation and Cancer.—Since no race of mankind is exempt, the association of cancer with forms of chronic irritation* having nothing in common beyond their liability to produce chronic ulceration, chronic inflammation, or prolonged attempts at repair, is a fact of more moment than any futile discussion of the relative liability of different races of mankind. Carcinoma of the skin of the abdomen is practically unknown in Europe, yet it is most extraordinarily frequent in Kashmir, because the natives there wear next to the skin an oven containing burning charcoal. I show photos of this charcoal oven, of Kashmiris wearing and using it, and also of the typical squamous-celled carcinoma with metastases resulting from the native practice. Carcinoma of the floor of the mouth is rare in European women, although not uncommon in men; but in Ceylon and India generally the women suffer to a high degree from carcinoma of the inside of the mouth. This is due to the chewing of betel-nut and the practice of sleeping with the plug in the mouth; in the course of time carcinoma develops at the site so irritated. Without elaborating instances it may be stated, in short, that the incident of cancer on the surface of the body in different races of mankind is influenced, on the whole, not so much by innate racial peculiarities, or differences in climate, soil, and diet, as determined by external irritants. The results of the study of the comparative incidence of cancer in man are of fundamental importance. They enhance the significance of two conclusions from histological and pathological investigation in Europeans; first, that cancer can arise locally in a circumscribed area, and second, that any part of the normal covering of the body may acquire cancerous properties. Hence it is also probable that more than one focus of origin, or even foci of different age, may be contained in a circumscribed area. Therefore, although the inception of malignant new growths is confined to a circumscribed area, and continued growth proceeds only from the resources of the tumor-cells comprised in it, successive augmentations in the extent of the primary area by apposition cannot be excluded in all cases.

I must point out emphatically that I do not feel justified at present in assigning anything more than an indirect or mediate etiological significance to chronic irritation and to other exogenous factors. The significance of chronic irritation is qualified by the fact of its not occasioning cancer in all individuals who subject, with equal intensity, identical parts of the body to its influence. An active prolonged or an intermittent process of regeneration and repair is intercalated before the development of cancer in tissues subject to chronic irritation. Observations which I shall have to refer to later, have shown that there is an immense variety of carcinoma cells, all descended from normal cells, some of which pass into one another while others do not, and are able to maintain their characteristics for prolonged periods during the artificial propagation of tumors. The same holds for sarcoma cells. It is not inconceivable that under the influences of chronic irritation the cells in a tissue undergoing a prolonged or intermittent process of regeneration and repair exhibit similar variations, some ultimately capable of advancing to malignant cells and others not. The end result is possibly determined by a combination of these factors with constitutional conditions. In this way it becomes intelligible why the irritants themselves have so little in common. Haaland's observations in the laboratory of the Imperial Cancer Research Fund appear to have thrown much light on this subject. His studies on our tumor "37" concerning the experimental development of sarcoma—a phenomenon first recorded by Ehrlich and Apolant—have yielded evidence that repeated transplantation in some cases aids the process. At the time when carcinoma sarcomatodes was obtained by this means, no progress had taken place in the mouse yielding the mother material. From a review of the whole circumstances Haaland's observations point to the sarcomatous change arising in the transformation of a few, perhaps isolated, normal connective tissue cells. Whether the process consists in a succession of small variations whereby they become transplantable and ultimately progress into sarcoma cells, or is a sudden acquisition of sarcomatous properties is not definitely settled. It would appear that the repeated transplantation was of moment, in some cases, in effecting the transformation, partly by maintaining the cells in a continued or intermittent state of regeneration, partly by affording a means of selecting and perpetuating variations more capable of growth. This conclusion is put forward tentatively, for our studies on tumor "37" are still continuing, and a comparison will have to be made with another of our tumors "100" which Russell has found leads to the development of sarcoma. The behavior of these two tumors as regards the development of sarcoma does not at present appear to be identical in all details, differing most prominently in that, whereas repeated transplantation aids the process for tumor "37," it hinders its advance in the case of tumor "100". Sarcoma development can be obtained constantly

*For example, *physical injury*, as in fracture of bone or in "brand" cancer," or the "horn core" of cattle, where squamous cell carcinoma develops at the root of the right horn to which a wagon is attached in India; *chemical*, as in paraffin, petroleum, arsenic, aniline, etc.; *radiant or actinic*, as in short clay pipe, the Kangri, x-ray, or where the skin over the shin-bones of locomotive drivers has been exposed for years to the direct action of heat; *infective*, as in bilharzia of the bladder, tubercle in old lupus scars; *Trepynema pallidum* in keratosis linguæ; tapeworms as recorded by Borrel; chronic inflammation and ulceration of all kinds, etc.

for tumor "100" provided growth is maintained for some 50 days in a single animal. Pure carcinomatous strains of both tumor "37" and tumor "100" have been maintained in propagation, so that it will be possible to harmonize their behavior, or to discover the nature of the differences if any really exist. I illustrate the experimental development of sarcoma in the course of the propagation of carcinoma by a series of slides, for tumors "37" and "100."

Hereditary, Congenital, and Infective Hypotheses of Cancer.—The question of the hereditary transmission of cancer has not been settled either one way or the other for man. The short duration of life in the mouse and the rapidity with which generation follows generation make it an ideal animal for the study of problems of heredity. For years we have devoted attention to breeding experiments with mice of cancerous stock. The starting points have been mice suffering naturally from the disease and relieved of their tumors by operation. In the first 400 mice, so bred, which lived over six months 30 cases of cancer appeared; the incidence of the disease continuing, however, to obey the law of age-incidence, without as yet giving any indication of in-born predisposition playing a part in determining either a local or a constitutional liability to the disease, or even so much as an enhanced suitability for inoculation. Therefore, it would appear that the disease, or the local and general predispositions which apparently exist, are always acquired, and, if so, may ultimately be found to be avoidable.

The pessimistic views entertained in regard to cancer are due largely to the wide dissemination of the ill-defined idea that malignant new growths, as a whole, being of "congenital origin" must inevitably compass the doom of many. This idea arises in the first place from a generalization of the fact that certain forms of cancer are undoubtedly associated with congenital abnormalities, and from neglect of the equally important fact, that the acquisition of malignant properties by their component tissues is just as much a problem as the development of cancer in adult issue. In the second place, it is due to seeking an analogy for the powers of growth of cancer in embryonic tissue. In the third place, it is founded on the assumption that the absence of histological differentiation in many cancers proved a biological resemblance to embryonic tissues previous to their differentiation, proved indeed a reversion to embryonic conditions.

The absence of any evidence of hereditary influences detracts much from hypotheses asserting a congenital origin for cancer. Other facts are even more emphatically opposed to them. The study of the incidence of cancer as determined by irritants in man, demonstrates that the generalization of the idea of a congenital or embryonic origin is incorrect. Neglecting cancer in animals—although generalizations to carry any weight at all must be extended to them—and to refer to but three examples in the case of man: Cancer of the skin of the abdomen is practically unknown in Europe, yet it is most extraordinarily frequent in Kashmir; this is not due to a distribution of congenital "germs" in the skin of the abdomen of Europeans and natives of India other than that in Kashmiris, but to the fact that the latter irritate the abdominal wall by wearing a charcoal oven round the waist and the former do not. Cancer of the floor of the mouth is rare in European women, although not uncommon in men; but in Ceylon and India generally, the women suffer to a high degree from cancer of the inside of the mouth. Again, this is not due to developmental differences between women in England and those in India, but to the fact that Indian women chew betel-nut and sleep with the plug in the cheek at the exact spot where cancer starts. In needle-women melanotic sarcoma often develops in the fingers at the site of frequent puncturing by the sewing-needle. If all forms of cancer are to be explained by the intervention of congenital germs then it must also be assumed that such germs are as uniformly distributed, *e. g.* over the surface of the body of all vertebrates as the skin is itself, and thus the explanation becomes no explanation at all.

The growth of cancer is essentially different from the growth of embryonic tissue, analogies with which were natural so long as the growth of cancer was put an end to by the death of individuals. Experiment has revealed that the growth of cancer is, however, a unique biological phenomenon, disobeying all the laws of growth of embryonic tissue in accordance with which organisms and organs attain to their specific dimensions. The growth of cancer also differs in that in many instances it is accompanied by cyclical alterations between phases of more pronounced histological differentiation and phases in which all histological differentiation is absent. Any progressive histological change in the growth of cancer is in the direction of a disappearance of these alterations of histological structure so that the histological differentiations exhibited at an earlier date are not manifested later.

When a carcinoma is transplanted, the blood-vessels and supporting connective tissue scaffolding are supplied afresh as a reaction elicited by the chemiotactic influences of the parenchyma cells. The stroma of all transplanted tumors should be uniform if their characteristic elements possessed primary undifferentiated embryonic properties. On the contrary, tumors without any apparent histological differentiation elicit distinctive new vascular and connective tissue scaffoldings. The peculiarities of the stroma of different tumors remain constant during propagation. The fact indicates that the cells of malignant new growths, even when showing little or no indication of histological differentiation in the direction of any fully formed tissue, still possess permanent characters of a less obvious kind, and these characters are of the nature of specializations or differentiations analogous to those which we recognize as histological differentiations. Of over sixty propagable carcinomata growing in our laboratory it can be said that no single one is an exact duplicate of another. The cancer cells are, therefore, specialized and not undifferentiated cells. In the phenomena of induced resistance to the inoculation of cancer, especially in the specificities of immunity following the absorption of normal or cancer tissues, there is much that is opposed to the assumption that tumor cells are embryonic. Alternations in the rate of growth occur unlike anything known in the growth of embryos. In short, the interpretation of the absence of morphological differentiation as indicating a biological similarity of tumor cells to embryonic cells was due to the limitations of histological methods, which were insufficient to reveal the fundamentally different biological properties of cancer cells indistinguishable by their aid.

If pathological anatomists have in the past often

pointed out the difficulties in the way of drawing analogies between cancer and infective diseases, the comparative and experimental work of the past seven years has demonstrated that cancer has no analogy with *any known form* of infective disease. The force of this demonstration has appealed even to the staunchest supporters of a parasitic etiology for cancer, and has obliged them so to modify their opinions that I do not propose to discuss in detail the *petitio principii* into which they have been coerced, except with regard to the alleged occurrence of epidemics of cancer in rats, mice, and trout. Many tens of thousands of mice suffering from cancer have been under the most stringent observation in our laboratory. If cancer were communicable, animals housed along with those naturally suffering from or inoculated with cancer would be the first to suffer. In an experience extending over more than six years, *i. e.* more than three times the average length of a mouse's life, exhaustive investigation during which some 200,000 mice have been inoculated, has shown that this risk does not exist. Those handling the animals incur still less risk in passing many hours daily dealing with cancerous animals in a room in which 10,000 of such mice and rats are usually housed at one time. If such a "cancer-house" as never before existed has no dangers to human beings who spend their days in it, *a fortiori* other persons have no ground for apprehension that the ubiquity of cancer implies its transmission either directly or indirectly from animals to man, or *vice versa*. In corresponding observations on mice suffering from spontaneous cancer no case of transference from mouse to mouse has occurred. Cancer is ubiquitous, yet there are the most striking limitations to its conveyance from one individual to another, continued growth taking place after inoculation into animals of the same species only. Inoculation is only successful by the implantation of living cells, but experiments show that this risk is negligible if it exists at all in nature.

Epidemics of cancer have been alleged to occur in the establishments of breeders of rats and mice, notwithstanding that investigations made under the much more satisfactory conditions obtaining for man, have not given any statistical evidence of the epidemic or endemic occurrence of the disease. Our experience of such alleged epidemics may be illustrated by the proportions of cases of cancer to total numbers of mice supplied to us by four breeding establishments from January 1, 1906, to October 21, 1907.

Breeding Establishments	A	B	C	D
Tumor mice	10	6	35	18
Total mice	1302	1547	9698	11842

The number of tumors occurring in these stocks of mice has been determined solely by the number of mice of "cancer-age" under observation. This is brought out particularly clearly in the difference between the age-constitution of the stock of Mr. C. and Mr. D., since the stock of the latter contains constantly a much higher proportion of young animals, and he supplied us with most of our young mice. Further, if we note the dates on which tumors are sent to us and arrange them in columns we find that the crops of tumors coincide with the ageing of groups of mice. Thus, those aggregations of cases, loosely called "epidemics" by too enthusiastic advocates of a parasitic origin for cancer are really evidence of the importance of knowing the age-constitution of the mouse population in which the cases occurred, as pointed out earlier when speaking of the age-incidence of cancer.

Metabolism, and Vita Propria of Tumor Cells.—We have often pointed out from 1903 onwards, that the artificial propagation of cancer gave ideal facilities for studying the problems of its apparently continuous growth, particularly because the same parenchyma could be studied over any requisite length of time, and under different experimental conditions. These advantages apply with even greater force to the study of metabolism, and the relations of tumors to their hosts when living under varying experimental conditions. The relation of propagated tumors to the animals bearing them has been shown by Cramer to be analogous to that obtaining between the fetus in utero and the mother, only still greater quantities of tissue are built up. There is no evidence of toxic products injurious to the hosts; on the contrary, there is a compensatorily enhanced activity on their part, as revealed by Cramer's and Copeman and Hake's study of the gastric secretion, and by Cramer's investigations on the gaseous metabolism. In the end, however, compensation breaks down, and, finally, the tumors live at the expense of the host. When this stage is reached the animals speedily die. It appears that a definite ratio obtains between the weight of tumor and the weight of the animal supporting it without disturbance of health. If the weight of tumor exceeds this relationship the animal quickly suffers and succumbs. Compensation may be upset much more rapidly by taking advantage of the fact that the rate of increase of some tumors is proportional to the dose of tumor material inoculated. In this way it can be shown that the terminal result is due to the greater number of cells demanding food, and not to a greater avidity for it, and that death is not due to poisons.

When very young animals are made to bear rapidly growing tumors they remain dwarfs, the whole increase in weight the animals should show by a given age being made up of tumor. Medigreceanu's analysis of the relations of the different organs to tumor growth shows that, when the animal remains a dwarf, individual organs, *e. g.* the heart, liver, kidneys, lungs, attain to adult size, so that they are hypertrophied as regards the mouse. The mouse, in short, is turned into an assimilative and excretory apparatus for the tumor. Murray has shown that, when rapidly growing propagable tumors are inoculated into mice with spontaneous tumors which, as is well known, are rarely able to establish themselves in normal mice, the spontaneous tumor of the mouse herself outstrips the propagable tumor. Mice which have cured themselves of rapidly growing tumors, transplantable with ease, have, on the one hand, developed spontaneous tumors of their own, and the latter, on the other hand, could be transplanted into normal mice only with difficulty, or not at all. Therefore, transplantability is not determined solely by the rate of growth or the degree of avidity for food. I may merely allude to other detailed investigations which are being conducted by Cramer into the general metabolism and its relation to the chemistry of the cancer cell, and to the fact that the cells of certain of our rapidly growing mouse tumors have been found by Abderhalden, in conjunction with Medigreceanu, to split up some synthetised polypeptides

more rapidly than normal tissues do. As yet we have not got much beyond defining, that the cancer cell has many of the properties of rapidly growing tissue, without containing anything extraneous, and without secreting anything directly deleterious to the organism. In these ways, and in a variety of others, our knowledge of the nature of cancer growth and cancer metabolism is being advanced with so great exactness that the old vague conceptions of disturbance of cell equilibrium, put forward to explain the apparently continuous growth of cancer, will ultimately be replaced by precise conceptions of the process, as the following additional facts on tumor growth already promise. In 1905 we described cyclical alternations in the energy of growth of Jensen's tumor. Since then we have been able to confirm these observations on practically every one of the 60 propagable mouse tumors now growing in the laboratory. The later investigation of the phenomena of the alternation of positive and negative phases of growth, has shown that cyclical changes in the cancer-cell are revealed in a variety of ways as follows: (1) rise and fall in the percentage of successful inoculations; (2) rapid and slow growth of the tumors in different series, and in the individual tumors of a single series; (3) transitory cessation of growth; (4) alternating susceptibility of the tumor cells to dosage, and particularly to the greater or less degree of simultaneous immunisation depending upon the latter; (5) Murray has drawn attention to cyclical alternations in the histological structure from alveolar to acinous and *vice versa*. I exhibit a series of slides illustrating these points in the *vita propria* of tumor cells. It is clear that, by these alternating properties of the tumor cells, an explanation is afforded of the varied histological picture different parts of the same tumor often exhibit, as well as of the erratic clinical course of cancer in man. In the human subject there are corresponding fluctuations in the growth of cancer. In one part of a tumor growth is proceeding rapidly, in another part slowly. Periods of exacerbation alternate with periods of melioration. Further, secondary nodules of growth are known to disappear while others are growing, and occasionally primary growths have disappeared. The observations made on mice emphasize the importance of those clinical features, largely discredited in the human subject, since it was impossible to resolve them into the orderly sequence which the prolonged observation of the growth and structure of propagable tumors has permitted. These studies on the *vita propria* of the cancer-cell makes it apparent that its secrets are being penetrated gradually. I have already pointed out that, of our 60 mammary tumors capable of continuous propagation under uniform experimental conditions, not one is a duplicate of another; nevertheless, they all appear to have one feature in common, for the biological properties of their cells alternate in the ways I have enumerated, and, therefore, something fundamental is revealed by the cyclical fluctuations in their general biological behavior, structure, and rate of growth. The cyclical alternations in the percentage of successful inoculations, and in the negative and positive phases of the rates of growth of the resulting tumors, are most impressive. I venture to suggest as an incentive to further investigation the solution of the problem: Are tumor-cells, in recovering the enhanced powers of proliferation they exhibit in the positive phase of growth, but imitating the process by which normal cells passed into cancer cells?

Tumor-Cells as Indicators of the Nature of the "Soil" Offered Them.—In order to penetrate to the finer relations existing between tumors and their hosts, we are obliged to rely upon the behavior of living tumor-cells after placing them under varying experimental conditions. The experimental conditions I propose to consider are those that living animals offer. The living cancer-cell indicates the condition of the "soil" into which it is implanted; in other words, the cancer-cell is the reagent, or "indicator," and the living mouse is the test-tube, containing something to be tested. In all experiments of this kind it is well to bear in mind the distinctions which may, and usually do, obtain between reactions *in vitro* and *in vivo*. The glass test-tube is, or ought to be, indifferent; breaking off a piece and casting it into the contents should not alter the conditions. In the *in vivo* experiments, which are alone possible in the case of cancer, the mouse is the living test-tube, and it is not indifferent; removing a piece and, so to say, incorporating it with the contents is not only not an indifferent procedure, but, as Woglom has shown, is one of the most efficacious ways of demonstrating certain of the reactions revealed by using the living cancer cell as an "indicator."

I have alluded to the varying qualities of tumor cells even under uniform conditions, and it may seem strange to emphasize their experimental importance, when appraising the significance of the results of attempts to modify experimentally, the behavior of a tumor, by changing the condition of the "soil" offered them for growth. Nevertheless, together with many other technicalities of the methods of experimentation, they have been almost universally ignored in the race for priority of publishing evidence of immunity against cancer. Much of what has been written on immunity, or resistance of mice to the inoculation of cancer, would not have been published had the authors studied sufficiently the varying qualities of tumor cells and the influences of other uncontrollable and controllable factors, as an investigation necessarily preliminary to claiming that they had immunized mice against inoculation, had vaccinated them against its attack, or had actually cured them of it. We spent three years studying the fluctuating growth and other varying qualities of the tumor cells, the influences of dose of tumor, age and weight of mice, time intervals, and the effect of injuring or actually grinding down tumor and normal tissue, in order that our attempts to modify tumor growth should be conducted with the precautions necessary to avoid experimental fallacies. In this way we cleared up the contradictions we had recorded between observations made *in vitro* and *in vivo* with immune sera, as well as accounted for the apparent curative results obtained by injecting immune sera into animals with tumors, before we devoted any communication exclusively to the subject of immunity. When we published definite statements in 1906 Clowes had already claimed (1905) to have demonstrated antibodies directed against the cancer-cell, and Ehrlich had set up (1906) the doctrines of atreptic immunity and pan-immunity. Our observations are opposed both to Clowes' and to Ehrlich's interpretations of their experiments. We were able to show at once that immunity to the inoculation of mouse cancer could be produced by both the absorption of cancer tissue and of normal tissue of the

mouse, but not by cancer tissue or normal tissue of strange species. We also showed that the resistance which tumor mice show to a secondary inoculation was actively induced, and that resistance was specific for different tumors, even when of the same organ. These results were arrived at by using exact quantitative methods, and by employing the other precautions already mentioned. Haaland came independently to the conclusion that the resistance was specific for different tumors, and Borrel and Bridré have arrived at the same conclusion.

Apparent contradictions still exist between some of our conclusions and those of other workers, but I believe they are mainly if not wholly explicable by neglect of some of the precautions we have so often emphasized. Two of these precautions may be alluded to in more detail. The differences obtaining between young and old mice in their suitability for inoculation and growth are very important. You can easily appreciate how if a tumor is sent from one country to another and there transplanted into old mice, a negative result may be obtained which it would be wrong to assign to differences in race of mice. I have a chart of such an experiment where some of the difference in the growth of an English tumor in German mice is seen to be certainly due to the higher age of the latter. The effect is not so great as to lead to an entirely negative result because the tumor cells were in the positive phase of growth, but on the next slide they are shown on the negative phase of the growth and not a single tumor developed in the strange soil. Differences in the mice of different countries exist, however, but whether these differences in the mice of different countries are racial differences or are less permanent and due to diet and environment is not yet definitely settled. They do not exist for all tumors, as the slide I show of the growth of Borrel's tumor "B" demonstrates. This French tumor grew at once in 100 per cent when inoculated into English mice and as the slide shows, yielded large rapidly growing tumors. It is a general property of all tumors that they grow not so well or not at all in old mice. You can easily appreciate that if the middle aged and old mice which were negative to a first inoculation had been reinoculated, they would have proved resistant again to any tumor. The resistance would appear to be general, for its specific nature would be concealed. The same appearance of general immunity can be obtained after inoculating the tumors or tissues of strange species of animals into sufficiently aged mice.

We have often pointed out the importance of the dose of tumor material inoculated. Together with the consideration of age it merits equally emphatic mention if the results of other investigators are to be harmonized with our own: this applies both to doses used to induce immunity and to doses used to test for its existence. Any dose of tumor will not suffice to produce a new tumor at the site of inoculation. The dose may be too large, so that only transitory growths develop, or, it may be too small, so that no growth is evident. When a tumor develops, the dose from which it started is not a matter of indifference if a later inoculation is to be made into the same series of animals. A chart I show demonstrates a diminution in the success of inoculation with diminishing doses, and a corresponding diminution in the degree of resistance of the mice to a second inoculation. The phenomena can be explained only by the primary inoculation having induced an active immunity concomitant with the establishment and the growth of the tumors. This concomitant autoimmunisation may be very perfect as is shown in a chart taken from Haaland's experiments with our tumor 206. In the case of this tumor it is so complete that every mouse cures itself of its growth. The resistance induced against a reinoculation of the same tumor is more complete than against other tumors. The resistance in this sense is specific, and the conditions of growth are also specific, since a tumor of different nature, although of the same origin will grow in mice which are completely protected against a reinoculation of the tumor first inoculated. The lesser degree of protection which one kind of mouse tumor induces against other kinds is due probably not to cancer-tissue as such, but to its properties *quâ* mouse tissue.

A sarcoma of a cat or rat vaccinated into a mouse, lacks the power of protecting it against subsequent inoculation of mouse sarcoma. I have a chart illustrating the absence of immunity when rats have been previously inoculated, with cat and with mouse sarcoma. The same holds for corresponding experiments with carcinoma. In short, animals can be rendered unsuitable for the inoculation and growth of cancer only by treating them with malignant new growths, or with normal tissues of their own species. In the latter case the degree of resistance corresponds closely to the relationship between the normal tissue vaccinated and the tumor subsequently inoculated. The skin protests best against skin cancer, and the figures of the site of inoculation in a control and in an immune mouse demonstrate the efficiency of the protection. These facts refer us back again to the transplantation of cancer being limited to animals of their own species, and together with them demonstrate the retention by malignant new growths of the tissue characters of a species. The malignant new growths of different species of animal resemble one another just as much, and differ just as much, as their respective organs and tissues do, *e. g.*, as the liver and lungs of man resemble and differ from those organs of the mouse. The power of normal tissues to induce protection is not restricted to those obtained from other individuals. Woglom has shown that the absorption of a mouse's own tissues, *e. g.* of the spleen, effectively induces protection against subsequent inoculation.

The parallel between cancerous and normal tissue extends much further. Immunity or resistance is induced only by the inoculation of living tumor cells or of living normal cells. Haaland has made very elaborate investigations on this subject. He has found that cancer tissues and normal tissues are deprived entirely of their powers of inducing resistance if they are frozen and effectively crushed. I illustrate this parallel by a chart showing the protective power of living normal skin and its loss of power to induce protection after being disintegrated in this way. Immunity therefore does not appear to be induced by the chemical contents of the cells.

Another chart is of particular interest. It illustrates the action of radium upon normal and cancerous tissues without causing their disintegration. After exposure to radium for an interval within which no structural alteration can be observed in the tissues, either with the naked eye or microscopically, they may be completely deprived of their powers of growing and immunising. The abolition of these vital properties is here achieved with retention of the histological structure of the tissues

and of intactness of the cells, and the experiments demonstrate that the power to elicit these biological reactions is intimately bound up with, and dependent upon, the vital activities of the cells themselves.

Not only does no immunity follow the inoculation of effectively disintegrated material, but on the contrary the mice may thereby be made more suited for the growth of tumors. This hypersensitiveness is, however, not so specifically induced as resistance. It can be induced both by tumor and by normal tissue of strange species, and since resistance may follow the absorption of a mouse's own living tissues, it is also probable that hypersensitiveness may be induced by her own tissues when properly disintegrated.

The nature of the immunity to cancer is not yet fully elucidated. It has no analogy with anything known for the infective diseases. The hopes of obtaining an anticancer serum cautiously expressed by Jensen in 1903 have not yet been fulfilled. Further investigation of the action of the serum of immune animals both *in vitro* and *in vivo* has justified the cautious references we also made to the same subject in 1904 and 1905. Clowes' evidence of the presence of a specific antibody in the serum able to exercise a curative effect *in vivo*, and a lethal effect on the tumor cells *in vitro* stands alone. We have never ascribed to the action of antibodies, the beneficial effects which Jensen, Clowes, and we ourselves sometimes noted after the injection of the serum of immune animals. The action of immune serum *in vitro* has been found both by Flexner and ourselves to be just as injurious, but not more so, to the cancer-cell as is normal serum. It can be now stated with some confidence that animals which are absolutely protected against inoculation do not yield a serum which, when introduced into new animals, has a power of protecting them against inoculation; still less is there any evidence of immune sera having a power to cure animals of tumors already growing. Highly immune mothers apparently do not transfer immunity to their offspring as do animals immune to diphtheria or other poison of infective disease.

At present artificial resistance can be made efficacious mainly against the inoculation of grafts which speedily die in immunised animals. I show you a picture of the manner in which a normal mouse responds with a new connective tissue scaffolding, and the contrast that obtains in an immune animal which does not respond in this way. The most evident cause of the death of the grafts is that they cannot grow into an organized tissue and nourish themselves. We have explained the absence of the specific stroma reaction, necessary for a graft to develop into a tumor, by assuming that the chemiotactic properties of the cancer-cells are paralysed, so that they are no longer able to elicit the specific response on the part of the host. Russell has been able to demonstrate that this is the nature of the process. Working in our laboratory Da Fano has carried Russell's investigations further, and besides confirming that the specific connective tissue and vascular scaffolding supplied by a normal is not supplied by an immune animal, Da Fano has shown that the entire connective-tissue system of the animal responds during the processes both of spontaneous healing and of immunisation. Any subsequent inoculation fails to elicit the response necessary for continued growth. It is not intended to deny that changes in the blood-plasma accompany the acquirement of resistance or immunity, but while it is difficult to conceive of so complete a constitutional change occurring without this intervention, the constitutional changes throughout the connective tissues prove that changes in the blood-plasma are not solely responsible, and that the immunity is not purely of a humoral nature but to a large extent cellular. An explanation is thus afforded of the negative results which have hitherto attended all Borrel's, Ehrlich's, Flexner's, Jensen's, and our own attempts to obtain an anticancerous serum. I would merely point out that the connective-tissue changes observed in mice during the absorption of tumor tissue are parallel to what has been described for spontaneous healing in man, for example, by Orth.

Conclusion.—From a survey of cancer in man and animals the following conclusions stand out. The first confirms that at which Waldeyer arrived in 1867 from his studies on man; the cells of vertebrates, *e. g.* of the skin, possess or acquire some property or properties in common, in virtue of which they may be transformed into cancer cells under what appear to be very different circumstances. The second is the application of the law of age-incidence to vertebrates generally, irrespective of the absolute duration of life. Third, the disease originates in a circumscribed area. Fourth, when all due weight is given to this origin in cells within a circumscribed area, the relation between these cells and the organism as a whole is of moment. To these conclusions the experimental reproduction of all the lesions of cancer has enabled us to add the many others, I have related to you.

At this early date it is sufficient to have thrown a little light on four aspects of the etiology of cancer. First on the constitutional conditions favorable and unfavorable for the growth of cancer-cells. Second, on how cancer-cells after having passed into a phase of low proliferative energy may reacquire high powers of proliferation and of resistance to changes in their environment. Third, on the possible nature of the indirect association irritants have to the disease. Fourth, the cancer cells, even when of the same organ have been resolved into a larger number of varieties able to maintain their individuality than was previously conceivable. These varieties are of the nature of specialisations or differentiations unrecognizable by histological methods. Experiment has put many older explanations out of court. No evidence has been obtained in favor of an hereditary, congenital, or embryonic explanation of etiology, nor has any analogy been discovered with known forms of infective disease. I have illustrated how experiment is resolving the contradictions in the clinical behavior and in the results of surgical treatment of cancer into orderly sequence. If experiment has not solved many of the old problems, it has replaced them by new ones, which is a fair proof that progress is being made.

In the survey I have given of the progress of the experimental study of cancer I have had occasion to draw attention to the bearing of many of the results on purely biological matters, and it is well to conclude by emphasizing the comparative biological importance of cancer investigation. Seven years ago no one conceived it possible that portions of the mammalian organism could be kept growing for a period four times the length of life of the whole animal. But to-day the number of different kinds of tissues now being propagated separately, make it theoretically possible that the majority of

the tissues once they have acquired cancerous properties, may be so grown and segregated. In other words, a living animal can be analyzed into many of its living component tissues. The finer relations of various kinds of tissues to one another have been revealed by the application of the new methods. The biological alterations which living mammalian cells may undergo suddenly, as well as gradually, under the influence of experimental conditions, can be now studied. These and many other achievements in the field of general biology are the most important practical fruits which have accrued from the experimental study of cancer, upon which they have only indirect bearings. Ultimately they are bound to be of far-reaching general biological importance, although to-day they are merely the weapons that have been forged to attack cancer. Their further development, and their utilization for the solution of purely biological problems, will probably precede the solution of many of the problems surrounding the nature and causes of cancer. Having put before you a claim for the value of comparative and experimental investigation with the confidence that it is based on a sure foundation, and evidence that it is advancing our knowledge of the etiology and pathogeny of cancer, I crave your indulgence till time will enable these methods finally to clear up the cellular problems it has helped us to define so much more precisely than ever before.

YELLOW FEVER PROPHYLAXIS IN CUBA.*

By ARISTIDES AGRAMONTE, M.D.,
HAVANA, CUBA.
PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF HAVANA.

As the title of this paper suggests, it is not my aim or desire to enter upon a discussion of the usual prophylactic measures as they have been generally applied in the various campaigns against yellow fever epidemics, but to limit its scope within certain boundaries, referring principally to conditions which, because of their peculiarity, have demanded a different course of action from that followed elsewhere. It is also my purpose to bring out before this Congress in an unmistakable manner, how much better we are prepared than any of the other nations of the American continents to encounter and defeat yellow fever, since from a sanitary point of view we have been the cynosure of all eyes and our reputation in this respect has been maligned upon more than one occasion.

The topography of the island, no less than its geographical position, to say nothing of its international commercial activity and its proportionately large nonimmune population, renders our territory, if not less vulnerable to yellow fever invasion, certainly more favorable to its extinction than that of other countries of similar extent and ethnological conditions.

When you have kindly considered the actual sanitary measures here noted, which have been not only implanted but rigidly enforced and strictly and persistently maintained, you will not think it boastful on my part if I express the conviction that we shall have no more yellow fever epidemics in Cuba, provided, as I firmly believe will be the case, that the political conditions remain as favorable as they have been inaugurated by the present government.

In 1901 yellow fever infection disappeared from the island as the result of a campaign based solely upon the doctrine of mosquito transmission, carried out under the direction of Major W. C. Gorgas of the U. S. Army.

Until the fall of 1905 no more cases of yellow fever were seen in Cuba, except those introduced from Mexico or South America, which were so carefully taken care of, that no secondary cases ever developed from any of them. During this period (from February, 1901, to October, 1905) the Republic was inaugurated (May, 1902) under the best auspices; the flow of immigration, particularly from Spain (83 per cent.), increased tenfold and the new Central Railroad brought one end of the island into close communication with the other, stimulating industrial enterprises, developing new towns and sugar plantations, establishing commercial intercourse and new routes of travel between parts of the island which formerly, for want of this great advance in its civilization, were as foreign to each other as distant islands in a great sea could have been, or as portions of territory separated by inaccessible mountains.

The first event served to give us an unwarranted sense of security, derived mainly from the natural enthusiasm caused by the achievement of national independence; the second proportionately increased our nonimmune population, already augmented by the birth of susceptible material, and the third very efficiently spread stegomyia from the longer coast towns to the interior and to the new centers of population, where formerly none were to be found.

The epidemic of yellow fever which developed in New Orleans in the summer of 1905 crept into our territory in October of the same year, so that from that date until December 24, 1908, 405 cases occurred. The accompanying maps show the number

FIG. 1.—Number and distribution of yellow fever cases during 1905, October to December, inclusive (77 cases).

*Paper read before the Sixteenth International Medical Congress, Budapest, August 29-September 4, 1909.

and distribution of the cases (Figs. 1, 2, 3, and 4).

No case of yellow fever has occurred in 1909.

In the presence of these facts and in order to make my subject clearer, I shall divide it into two parts: firstly, prophylactic measures of a general or indirect character, and, secondly, those which have been directly employed against the occurrence or in the presence of yellow fever cases.

Indirect Measures.

A National Health Department.—Until August, 1907, the sanitary organization of the Republic consisted of two divisions, a maritime or quarantine and a terrestrial sanitary department, each under a different chief and in more than one respect independent the one from the other. Besides this, there were local health boards which controlled the sanitary affairs of each municipality according to the means provided by the same.

The numerous difficulties which this system continually presented in the improvement of the sanitary service were fortunately done away with by the decree which united all the sanitary authorities under one head, abolishing the local boards and appointing one local health officer to take their place in each municipality. The results were most satisfactory from the administrative standpoint, and the conflict of authority which previously so frequently interfered with the carrying out of urgent sanitary measures was permanently removed.

But this was only the first step taken in the direction of establishing a National Health Department, which under the new Organic Law of the Executive power was created; its chief is the Secretary of Public Health and Charities, a member of the Cabinet, thus placing under one head all the sanitary administration of the Republic.

As a prophylactic measure this innovation has been of the greatest importance, since the sanitary work of every city and town in the Island is now under the control of a central power; the methods have become uniform and the officials are all trained in the same direction.

Any case, in any part of the Island, remotely suspicious of any of the quarantinable diseases is immediately reported to the Director of Health, who orders the preventive measures which may not have been implanted and either goes himself or sends a commissioner (generally one specially trained in the diagnosis and prophylaxis of the disease in question), to carry out all sanitary work until the danger of the disease becoming epidemic has passed. This was done in Cienfuegos (1907), where only 75 cases developed in a nonimmune population of more than 4,000; also at Daiquiri, Oriente (1908), where only twenty cases occurred in a nonimmune mining population of more than 3,000 men. These were the largest epidemic foci since the reorganization, and they show what excellent results can be obtained by immediate concerted action on the part of the sanitary authorities.

Fig. 2.—Number and distribution of yellow fever cases during 1906 (112 cases).

Fig. 3.—Number and distribution of yellow fever cases during 1907 (167 cases).

The Establishing of Quarantine.—I believe that quarantine can be of but comparative worth against yellow fever infection so long as any value is placed upon the certificates of immunity presented by passengers. In the majority of instances, cases in the incubation period have entered the various countries by means of certificates of immunity obtained in some fraudulent manner. If every country, like Cuba, kept a strict record of the cases of yellow

fever, then we could put some real value upon the certificates that they issued.

In 1905 a close quarantine was established against southern ports of the United States, and yet the infection which was then waning in New Orleans invaded our territory in October of that year, and has been the source of great expense and worry to our government. An absolutely closed quarantine against infected ports, of course, is quite effective, and if no passengers coming therefrom are allowed to go at large before six days after arriving, and the vessel is not permitted to approach within 200 meters of the shore, no danger can be expected from them; but such measures cannot be applied except in accordance with laws prescribed in sanitary treaties, and even so are sure to cause great inconvenience to commerce and travel.

Isolation of Suspected Cases.—In yellow fever, isolation means not only segregation but also absolute defense against mosquitos. More than thirty cases (33) have been imported from Mexico and South American ports without a single secondary case developing. They were all taken ashore and carried to Las Animas Hospital, each being protected by a mosquito bar all the way from the ship to the hospital. Every febrile case in a nonimmune arriving from an infected port is treated in the same way; no danger is courted by attempting to establish the diagnosis before taking all precautions to avoid possibility of further infection.

At the hospital the conditions to insure absolute safety could hardly be improved upon. Every room is there separated by wire screen doors from the contiguous rooms and all the windows are similarly protected; outside doors are vestibuled and the premises are disinfected at regular intervals to destroy all kinds of insect life which they may harbor.

In the other cities and towns all suspicious cases are immediately taken into properly screened rooms until the definite diagnosis is made. Every hospital in the Island, public or private, has one or more rooms thus prepared for the isolation of malarial or yellow fever cases.

Registration of Nonimmunes.—About 60,000 men, nonimmunes mostly, are registered as members of the various Spanish clubs or societies in the city of Havana, for the medical attention of which there are five private hospitals, equipped with the latest and best that can be obtained in the way of apparatus, surgical instruments, electrical appliances and hospital supplies of all kinds. Each hospital was expressly built for the purpose in an unexcelled locality and is attended by a medical staff drawn from the best talent that the country affords.

These 60,000 men are in an indirect manner under the control of the Sanitary Department, for whenever a case of fever occurs among them the patient is taken into a specially screened department of the hospital or santorium to which he belongs, and is there seen at once by a sanitary inspector who daily visits the institution for the purpose of selecting all cases which in his opinion may be even remotely suspicious of yellow fever. All cases of icterus or albuminuria are particularly investigated and all are referred to the Infectious Diseases Commission for further study and final diagnosis.

Since the last census has demonstated the presence of 74,000 white foreigners in Havana, it may be readily understood what great aid is rendered by these societies, which register about 60,000 members, in providing sanitary control over a large proportion of the nonimmune population.

I may add that in all the cities and larger towns of the Island there are societies or clubs analogous to the above mentioned, constituted mainly by Spanish business men and their clerks. They each have a sanatorium, more or less generously equipped, but from a sanitary standpoint all are equally efficient

Fig. 4.—Number and distribution of yellow fever cases during 1908 (48 cases).

in helping to discover cases of yellow fever or those that may be suspicious of yellow fever.

The Havana institutions have extended their field of action to the neighboring towns, and enroll members from the country, covering considerable territory. Spanish immigrants rarely fail to inscribe their names in one or other of these societies immediately they arrive, and it is needless to say that the government encourages this in all cases.

The Work of Special Commissioners.—The Sanitary Department has in its service men whose scientific reputation and peculiar ability in connection with the prophylaxis of yellow fever are well recognized. Whenever a case is reported from any part of the Island, one of these men hurries to the spot and, in the capacity of special commissioner, assumes charge of all sanitary measures, establishes quarantine if necessary, and in every manner essays to extinguish the focus of infection. If the history of the case and the symptoms are obscure, he studies the subject thoroughly until every vestige of suspicion disappears.

It is not my place to eulogize the work of these men, but there is no doubt in the mind of the Cuban sanitary authorities that it was mainly through their personal effort, their enthusiasm, and their thor-

oughness, that the late foci of infection were eradicated.

Direct Measures.

Destruction of Mosquito Larvæ.—A house to house inspection, with reinspections every ten days by men who have acquired remarkable ability in this line of work, insures the discovery of mosquito-breeding places wherever they may develop. The most unlikely places are sometimes found to contain deposits of water in which the stegomyia mosquitos may breed; now and then it is found that mosquitos have laid eggs in them and the larvæ thus developed are destroyed.

Besides this constant inspection, we have several brigades of men whose duty is to collect all tin cans, bottles, and broken glass which may become a breeding-place of larvæ by holding water for a sufficient period of time. These brigades carry out their work in the fields around the city and in the empty lots where the above-mentioned articles are often thrown by careless or indifferent neighbors.

A fine is imposed upon every tenant in whose house larvæ are found, careful instructions to avoid this having been previously widely circulated in the form of leaflets and published broadcast in the daily press.

The necessary water tanks or barrels, where water for household purposes cannot be provided in any other way, are compelled to be kept closed or covered with metallic gauze of 16 mesh to the inch. This procedure is well enough in the case of water tanks on the roof of houses or such single deposits of water, but in rural districts, where every house must have two or more barrels for the purpose, the expense of covering all deposits reaches a considerable sum, as the metallic gauze, through constant handling, soon becomes torn and therefore absolutely useless. A very good expedient was resorted to in these cases. I refer to the introduction of fresh water fish into the barrels, the local sanitary office undertaking to distribute the fish free of charge and to renew the supply as often as it becomes necessary. No larvæ can develop in water containing these fish, and in the localities where they are thus employed, the inspectors in their periodic visits see that every water barrel or tank contains a number of them.

Upon a large scale the anti-larvæ campaign is carried out by pouring crude petroleum into pools and natural deposits of water or depressions of the soil which may become so, and by filling them up or leveling them, as the case may be.

Destruction of Mosquitos.—The destruction of mosquitos is undertaken as soon as notice is received of a case of yellow fever; it is often carried out whenever a definite diagnosis cannot be arrived at within twenty-four hours after knowledge of the case is obtained.

The methods employed by our sanitary authorities have been gradually perfected through constant training, extended over several years, and the men engaged in the work have acquired such dexterity in the handling of minute details that uniform and satisfactory results are regularly obtained.

There are many conditions peculiar in themselves that we have to deal with, depending upon the construction of the houses, the habits and customs of the people, etc. In the rural districts and among the poorer farmers, fumigation to be effective must embrace the whole house *en masse;* the hut or shack, which is usually of cheap material, full of holes and crevices, must be put under tarpaulin to prevent the diffusion of the insecticide gas. Figs. 5 and 6 give an idea of the kind of building which we often have to fumigate, and the way this is generally done.

Fig. 5.—Type of rural buildings to be fumigated.

Regarding the methods employed, I could do no better than to quote here part of an article published in the official bulletin of the Department of Public Health and Charities.

"The work of fumigation may be divided into two stages; first, the preparation of the building, and, second, the process of fumigation, properly speaking.

"(1) *Preparation of the Building for Fumigation.*—The first thing to be done on beginning the disinfection of a house is to close all the doors and windows which communicate with the outside, leaving only one door for the men to go in and out the building. If the house has porches, these are covered with canvas. When this has been done, paper is then pasted over all the crevices and fissures, first around the exterior doors and windows, afterwards around the interior ones. The house should be divided into different isolated rooms or compartments

for the purpose of fumigation. After this has been done, the apparatus necessary for the fumigation is introduced into the building and placed at the most convenient spots; all the drawers, presses, trunks, etc., should then be opened and the furniture separated about one foot from the walls of the different apartments. Following this, the fumigators are gradually lighted and the operator retreats in the direction of the one door of exit, taking care to cover all crevices around the doors of the different compartments as the fumigation proceeds. After having sealed the door of exit, the fumigation of the covered porches is started, taking care that the tarpaulin which surrounds them is hermetically closed.

"Metallic gauze cages containing mosquitos are often placed in different parts of the house to test the efficacy of the fumigation.

When for some reason it is not possible to leave the drawers, presses, etc., open, their contents are taken out and shaken before being returned to their places, so that no mosquito may remain in the interior of the furniture.

"It is frequently necessary for the sanitary authorities to treat barracks with badly adjusted walls and roofs, huts, wooden buildings, etc., in this manner. In such cases it becomes necessary to cover the building completely with canvas, adjusting the borders tightly and pasting strips of heavy paper over them. The procedure is otherwise the same as that already indicated." (Figs 5 and 6).

(2) *The Process of Fumigation.*—For the destruction of mosquitos, sulphur, in the proportion of two pounds for every 1,000 cubic feet, is the most efficient substance employed. After three or four hours' burning, it causes the death of all the mosquitos in the apartment. The principal objection to the use of sulphur is that it attacks certain tissues, pictures and metals, but seldom in an irreparable manner. Metals may be protected by covering them with a thin layer of vaseline. For fumigation the sulphur in powder is placed on frying pans or other flat vessels, each of these within other receptacles containing water, into which the burning sulphur which sputters during the fumigation may fall. A small quantity of alcohol is poured over the sulphur to initiate the combustion and it is lighted at the moment of leaving the apartment. At the expiration of four hours, the outer doors are opened first, and progressively the interior ones, to allow the vapors of the sulphurous acid to escape.

Although many other insecticide gases have been recommended, we have employed sulphurous acid exclusively in dealing with mosquitos, and with the best results.

The Infectious Diseases Commission.—I have purposely left for the end of my paper the few remarks which I desire to make in presenting to you this important wheel in our sanitary machinery. Without going into an exposition of the value of its component (the names of some of its members—Guiteras, Finlay, Albertini,—are sufficient guarantee of the scientific proficiency of the whole), a few words may be not amiss to show what an important rôle it plays in our prophylaxis against yellow fever.

Whenever a suspicious case is reported, whether by our sanitary inspectors, from the Spanish sanatoria above referred to, or by private practitioners, the Commission is convened, sometimes within two hours, and the case is taken under consideration. The patient is examined from a clinical as well as a microscopical point of view, and if the patient has died before the meeting of the Commission, the body is autopsied so that a definitive diagnosis is firmly established.

Fig. 6.—Method of fumigating a rural hut. Completely covered.

With this procedure it is not probable that a case of yellow fever will pass unrecognized, and almost impossible for an epidemic of this disease again to develop in our country.

Comparisons are odious, regardless of the aim intended in their making; but since, as I have said, from a sanitary standpoint we have been in the public eye for several years, I cannot refrain from calling the attention of my hearers to the superiority of our organization when compared with that of our neighboring countries, including Mexico and the United States.

The latter, and more especially the States bordering on the Gulf of Mexico, depend almost exclusively upon quarantine measures to prevent the introduction of yellow fever; their towns are overrun by stegomyia mosquitos; the city of New Orleans, in Louisiana, which depends for its water supply upon the use of cisterns in every house, has failed

to keep them all properly covered, and mosquitos are to-day nearly as plentiful as before the dreadful epidemic of 1905. The nonimmune population is widely disseminated and in the hands of private practitioners, who will fail to recognize the first cases, or will hide them, as they did in the memorable summer of 1905. The same may be said of the other Southern States whose bugbear is yellow fever and whose protective mainstay is quarantine, the least useful measure which may be implanted in any country for its defense against said infection.

Mexico has been doing considerable work, and the city of Vera Cruz is no longer the pest hole of years ago; but those parts of the country distant from the centers of authority (Yucatan, Campeche) are very deficient in their sanitary organization, and the result of their campaign against yellow fever is far from satisfactory. Yet Mexico has instituted a house-to-house inspection, petrolizing brigades, and in all respects a good antimosquito campaign which, after all, is the basis of successful yellow fever prophylaxis.

Of Central American sanitary methods, the least said the better. Until political conditions improve in our sister republics, little can be expected from them in the way of sanitary reform.

It may be remarked that I have done little more than indicated the measures which have been so successful in eradicating yellow fever from our territory; my purpose has been mainly to stimulate discussion upon the matter, inasmuch as no doubt some of the countries here represented possess features not unlike those of the Island of Cuba, and also because, according to the program of this Section, no official report has been prepared upon this important subject of Tropical Medicine.

A FURTHER CONTRIBUTION TO OUR KNOWLEDGE OF INTESTINAL DYSPEPSIA.*

By MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The functional disturbances of the stomach have been thoroughly studied within the last thirty to forty years. The recognition of the various forms is now comparatively easy, and treatment therefore successful.

Clinicians are striving to attain similar results in the field of affections of the bowel, viz., a suitable subdivision of various disturbances of intestinal function, that can be clinically recognized and upon which treatment can be based.

Schmidt has tried to attribute the disturbances of intestinal digestion to impaired function of the various digestive glands (pancreas, liver, intestine). Such a classification, although very desirable, is hardly possible at present. The intestinal functions are so complex and the various glandular apparatuses contain ferments with such similar properties that it is even physiologically difficult to differentiate them strictly. How much harder would such a division be in pathological conditions?

Schmidt speaks of pancreas achylia, when quantities of undigested meat are found in the stool and the nuclei have not disappeared. Achylia means absence of juice. It may be, of course, that pancreatic juice is present, but that it is changed in character; or the possibility cannot be excluded that the pancreatic juice is normal, but is disturbed in its action through other causes. In describing pathological processes it is always best to proceed in a precise manner and to state only the facts which are definitely known or that can be deduced from the result of the investigation. I therefore proposed two or three years ago to subdivide the functional intestinal dyspepsias according to the result of the bead test into the following groups:

I. Digestive disturbances affecting all three classes of food stuffs (albumen, carbohydrates, fat) "Dyspepsia Intestinalis Universalis."

II. Digestive disturbances affecting only some of the food stuffs, "Dyspepsia Intestinalis Partialis."[1]

Regarding the bead test I first desire to answer Schmidt[2] when he says: "I also look upon Einhorn's bead test as a mutilation and not a simplification of my test diet method which besides is described as a "new method." I would like to say that my bead test has nothing to do with Schmidt's test diet. As is well known, Schmidt examines the feces after the test diet described by him. I, on the contrary, have introduced test substances that can be recovered after passing through the bowels and which can be given with any kind of diet. The fate of these test substances was first determined in physiological conditions, so that deviations from the normal are easily recognized. Schmidt says further: "It does not depend on whether a small particle of meat or potato is digested by the digestive organs, but whether the latter are equal to the normal requirements." To this I must answer, that if we know how the normal organism behaves towards the test substances, they will readily serve as indicators of the digestive activities; they represent a sample of how the food materials are utilized in the bowel.

I would like to add that the bead test has been of distinct value in my further investigations, and that I do not hesitate to recommend it to you warmly as useful and practical.

For both groups of diseases which can easily be recognized by the result of the bead test I would like to give some new examples.

The following two cases belong to group one:

Case I. April 24, 1909.—Mrs. U. G., about 40 years old, has complained for the last twelve years of pains in the abdomen and nausea. One and a half years ago a gastroenterostomy was done, after which she felt much better for about a year. For the last six months she has been again suffering and was about the same as before the operation. The patient complains of pains in the pyloric region and of nausea, which occurs off and on. There is obstinate constipation and severe pain after stool over the entire abdomen. Examination reveals slight sensitiveness to pressure over the entire abdomen, otherwise nothing abnormal can be found except ichthyosis of the skin. The bead test shows the reappearance of the string after sixty hours; everything is present except potato; thymus nuclei have disappeared.

Case II, April 18, 1909.—David C., 34 years old, salesman, had syphilis fourteen years ago, was a moderate drinker. He used to smoke considerably until two years ago. About nine months ago he suddenly became constipated for five days. Patient then took castor oil, after which his bowels kept running continuously until two weeks ago. He had from two to twelve movements daily. About two minutes before the movement would come patient

*Read before the International Medical Congress at Budapest, August 29 to September 4, 1909.

would experience a rolling in the pit of the stomach, and a gnawing, screwing sensation over the abdomen; it seemed to run up and down in his intestines. There were no pains or cramps with the movements. He always had a lot of wind, no belching, slept well, no headaches. For the last six weeks patient had pains in the stomach and abdomen. The latter would be so tender that the least weight on it would cause suffering. The physical examination reveals a condition of cardioptosis, hepatoptosis, and dilatation of the stomach. One hour after Ewald's test breakfast the gastric contents show absence of acids and ferments. The result of the digestive test capsule is as follows: the bead string is passed after fifteen hours, everything being present including nuclei.

To group II belong the following cases:

Case III. January 5, 1909.—Ike B., 30 years old, tailor, had always been troubled with the stomach and had a bowel movement four to five times daily after eating; always a small quantity at a time. At night he had a good deal of wind and must get up to get rid of it, as he could not pass it in the recumbent position. He had to get up once, twice, or three times during the night, but never less than once. He had more or less headache. The digestive bead test shows after thirty-six hours: half potato and thymus present; nuclei and everything else has disappeared. Examination of stomach contents shows absence of HCl, acidity = 26; rennet ferment present.

Case IV. April 3, 1908.—Miss Dorothy C., 24 years old, has always been perfectly well until four years ago. She then started to have occasional attacks of diarrhea, which alternate with constipation. The diarrhea usually occurs in the morning after breakfast; she occasionally has as many as five evacuations daily, sometimes accompanied with pains in the bowels. She suffers from gas and bloating, also from belching. She has pre-menstrual pain and occasionally headaches. At times there is nausea. Physical examination shows a normal condition of the chest and abdomen. The digestive bead test was recovered after nineteen hours; everything had disappeared except three quarter potato and a trace of thymus, nuclei disappeared.

Case V. June 24, 1908.—Miss Mary R. S., 28 years old, has always been fairly healthy except for an attack of acute nephritis eight years ago, following a cold. She had about four attacks of appendicitis always attended, as she says, with the formation of an abcess, which regularly broke into the rectum. She was operated upon for appendicitis about one year ago. Until about four years ago she always suffered from constipation. She then developed diarrhea, which has lasted ever since; she has between twenty and thirty movements daily. She complains of backache, nausea, cramps, pressure in the epigastrium, desire to go to the toilet, tenesmus, and fullness in the abdomen. She has a good deal of mucus in the bowel. She formerly weighed 150 pounds, but now only 112 pounds. The physical examination shows enteroptosis, both kidneys being movable, and tenderness along the colon. Digestive test capsule reappeared after fifty-three hours; fat entirely, potato one eighth present, everything else disappeared.

Case VI. April 17, 1909.—Miss Florence L., 22 years old, actress, has had scarlet fever, measles, and chicken pox in childhood. Three years ago she got diarrhea, which continued until she was so weak that she could not stand it any more. She at that time also vomited. She was very sore in the stomach, and had a continuous dull pain in the abdomen. Appetite now is good. Had formerly between twenty and thirty movements daily; now about two to four daily. Examination reveals a condition of enteroptosis, right movable kidney and atony of the stomach. The gastric contents show the presence of HCl and an acidity of 70. Result of the digestive bead test after fifteen hours: fat, potato, thymus present; nuclei and everything else have disappeared.

Case VII. March 30, 1909.—Dr. Maurice U., 31 years old, physician, has always been healthy until about three months ago, when he became troubled with diarrhea. This would yield to astringents, but would return upon stopping them. He had a great deal of pain and colic in the entire abdomen, just before his bowels would move. Whenever he would feel the desire to go to stool, he would have to go very quickly. He also had some rumbling in the bowel and a bad and always a dry taste in his mouth. There was no vomiting until about three days ago, when it occurred subsequent to smoking a heavy cigar. In the beginning he was very weak, and had about fifteen movements daily. The physical examination shows enlargement of the spleen and liver and dilatation of the stomach. Digestive test capsule reappears after twelve hours; potato, fat, thymus present, nuclei present.

Case VIII. September 25, 1908. Dr. I. J., 34 years old, singer, was always perfectly well until January, 1908. He then had an attack of nephrolithiasis. He suffered from gas, belching, and distress in the right hypochondrium. Bowels are always irregular. Stool is seldom hard, but usually mushy, sometimes light in color. He also has occasional pains over stomach. He smokes a great deal, drinks moderately. He had no syphillis, no headaches. The physical examination reveals a normal thorax and slight atony of the stomach. Examination of the gastric contents show HCl +, acidity = 80. Digestive test capsule reappears after seventeen and a half hours; potato, thymus, and one-third fat present; nuclei and everything else disappeared.

Case IX. September 9, 1908.—Joseph I., 50 years old, traveling salesman, has suffered for nine years from pains and pressure in the right lower abdomen. Two and a half years ago he was operated upon by Dr. Ill, and the appendix and gallbladder removed. Dr. Ill at that time told the patient that he had had intestinal adhesions. Since that time he complains in the same manner about that pressure. He feels a little better after eating. After one hour patient has the sensation of heat and congestion in the head; he is nervous and sick. This lasts until the next meal. Stools are constipated. Physical examination does not reveal anything abnormal. The stomach contents show the presence of free HCl, acidity = 50. The digestive test capsule is passed after nine hours; fat, potato, thymus present; nuclei and everything else disappeared.

Case X. March 23, 1909.—T. C. A., 51 years old, manufacturer, had yellow fever about twenty-seven years ago, pneumonia five years ago, syphilis thirty years ago. Formerly (for about eighteen years) used to drink daily a great deal of champagne. He has not smoked for five years. About two and a half years ago he started to have loose bowels, lack of appetite and loss of weight. He lost about thirty-five pounds. He found that if he ate anything he felt as if something was turning over

in him. He also had a faint sensation, and after that relief would come from belching, which was accompanied by a mouthful of saliva, that would come up. There was a feeling of fulness in his abdomen and rolling of wind on the right side. There always was a good deal of flatus. Examination of the fecal matter shows microscopically many muscle fibres, with striation and fat. The addition of iodine does not show the presence of free starch. There is achylia gastrica. The digestive test capsule showed: first test, after thirty-eight hours everything disappeared except meat and thymus, nuclei disappeared. Second test—a month later, when patient had considerably improved—after twenty-eight hours, everything disappeared except trace of thymus, nuclei disappeared.

Case XI. January 18, 1908.—Mrs. J. S. T., 34 years old, had pneumonia as a child of three. At nineteen she was very anemic. Five and a half years ago she had a child. Six weeks after confinement she experienced violent pain in the region of the appendix. Since then she has had similar attacks of pain, but not as severe as the first attack, every month at time of menstruation lasting two to three days and returning again after the tenth day from the start of menstruation, accompanied by severe headache over entire upper part of the head. The sensations are described as resembling those of a foreign body. Pains are getting less gradually. Since one year ago she has had a great deal of wind and an offensive breath. Digestive test capsule after twenty-four hours: meat and potato entirely, trace of fat, and half thymus are present. Nuclei and everything else have disappeared. Examination of stomach contents showed HCl +, acidity = 60.

Case XII. May, 1909.—Charles A., aged 47, has suffered with diarrhea ever since his birth. About twenty-one years ago patient began to have acute exacerbation of pain in the abdomen and particularly in the suprapubic region and diarrhea. At times he would have as many as fifteen stools a day. The stools were usually well formed but mixed with stringy mucus and at times contained blood, but often also diarrhic in character. With some of the attacks he would have a great deal of tenesmus. In the last five years the attacks have become less severe and frequent and he has gained seventy pounds. Examination of the gastric contents shows pronounced hyperchlorhydria. The digestive test capsule was given on May first. The bead string appeared in the stool after twenty-one hours. Everything had disappeared excepting fat and part of the thymus; no nuclei present.

It would of course be desirable to recognize clinically the various groups from their symptoms. I tried to ascertain whether in my cases of intestinal dyspepsia various types could be recognized from the subjective complaints, which would correspond with the result of the bead test. The following seemed to me to be of importance:

In the large group of distributed starch digestion the subjective symptoms are relatively insignificant. They consist mainly in complaints of fulness in the abdomen, frequent eructations, and expulsions of wind. The condition of the stomach varies. It may be normal, or hyperchlorhydria, subacidity, or achylia may exist. The group of disturbed meat digestion is characterized by the following syndrome. There is usually nausea present and a bad taste exists in the mouth; flatus are frequent and especially malodorant. The stool smells like decay. Patients may be well nourished, but they suffer very much. Diarrhea is not necessarily present. The class of distrubed fat digestion is characterized by the occurrence of attacks of sometimes intense abdominal pains; the stool is usually less consistent and of a lighter color. At times subjective symptoms are entirely absent. In the mixed groups the clinical picture is still harder to define because the various symptoms are less marked. In dyspepsia intestinalis universalis the clinical picture is rather severe: lack of appetite; general debility; usually, although not always, diarrhea is present. Abdominal pain is frequent. I have nearly always found achylia gastrica in this class. I fully agree with Schütz,[3] who maintains that in the majority of cases of intestinal dyspepsia there are mixed forms. The cases described above show this very plainly.

In the treatment of intestinal dyspepsia I am not in favor of eliminating the food stuffs, that are apparently poorly digested, but only of permitting a limited amount of these substances. In intestinal fermentation dyspepsia (disturbance of starch digestion) H. Meyer[4] and also Schmidt have lately advised the elimination of carbohydrates. In these chronic conditions I do not consider it advisable to forbid entirely a whole group of food stuffs. It is better to give it in decreased amounts. It is also advisable to give drugs which will facilitate the utilization of the food stuffs, whose digestibility is diminished in that particular patient. It is self-understood that our principal aim must be directed not to drugs but to a suitable arrangement of the diet.

In dyspepsia intestinalis universalis fluid and semi-fluid diets are indicated: milk, kumyss, raw and soft boiled eggs, meat powder, sanatogen, or similar preparations, soups, fine gruels, and leguminous vegetables in mashed form, crackers or zwieback, tea, cocoa, malt, and beer. As soon as the patient improves, the diet should be increased by adding fish, rice, mashed potatoes, and later white bread, scrambled eggs and a small quantity of tender meats.

After a rational treatment the bead test very soon shows a better result.

In the cases of partial intestinal dyspepsia the food stuff that is not so well digested should be reduced and should be given in finely subdivided form.

Just as in functional diseases of the stomach, a generally invigorating treatment is of great importance also in intestinal dyspepsias (where no organic trouble is present, as ulcers, cancer, etc.). Thus hydrotherapeutic and electro-therapeutic measures are of value. Climatic cures, life in the open air, free from care, will be of great assistance in accomplishing a considerable improvement or an entire restoration to health.

Tetanus.—L. G. Gunn of Dublin says that infection of the human tissues with tetanus is difficult, and that three conditions must be present before this can occur—the presence of the bacillus or spore of tetanus, the presence of a putrefactive organism, and the presence of dead animal tissue.—*The Dublin Journal of Medical Science.*

FORENSIC AND CLINICAL ASPECTS OF TRANSITORY FRENZY.*

By HARRIET C. B. ALEXANDER, A.B., M.D.,

CHICAGO.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE; FORMERLY ASSISTANT SUPERINTENDENT COOK COUNTY INSANE HOSPITAL.

Transitory frenzy, mania transitoria, folie transitoire, furore transitoria, transitorische Töbsucht is an acute frenzy which, developing suddenly and rapidly, soon reaches a climax with ungovernable spontaneous motor impulses and seemingly violent anger with complete absence of consciousness. The paroxysm does not change in intensity, but after a comparatively short time, rarely more than twelve hours, it subsides, usually after a profound sleep without leaving any recollection of events during the paroxysm, or without pathological cerebral change or mental defect. Were we to judge by popular reports where no forensic element is involved, such a condition must be exceedingly frequent. Such popular reports, however, take into account only the demonstrable superficial features and ignore the underlying factors. Careful clinical examination of many of these cases has shown the existence of paretic dementia, of the transformation stage of paranoia, of the frenzied stage of melancholia, of the psychic crises of tabes, of epilepsia larvata, and of a migraine-replacing psychosis. There are also underlying factors of congenital instability. Independently of these there exists a psychosis which as Calmeil, Marc, Hoffbauer, Rush, Ray, Tardieu, Griesinger, Kraft-Ebing, Le Grand du Saulle, Kiernan (J. G.), Diller, Spitzka (E. C.), Salemi-Pace, Piek, Schwartzer, Reich, Bjornstrom, and others have shown, is a condition of impaired consciousness characterized by either an intense manialike furor or confused hallucinosis. This condition from its explosive character and rapid disappearance is much less apt to come under the care of the alienist than the protracted psychoses. Careful analyses of many cases reported as delirium, cerebral congestion, cerebral hyperemia, and very acute temporary menigitis leaves no doubt that under these nosological misnomers transitory frenzy has been recorded. An excellent illustration of this psychosis is a case reported by Kiernan. The case is peculiarly valuable as the reporter was a witness of the attack itself. The patient had had a quarrel with her betrothed, after physical exhaustion following night-watching at her mother's bedside. On going to another apartment after the quarrel alluded to, she found that two live coals had fallen on a dress which she had been occupied in sewing for two days, and which some one had placed near the fire. Hereupon she fell into what was apparently a violent rage, tore the dress to pieces, attempted to smash the furniture, and continued violently excited for an hour when the reporter saw her. She was then in a condition of intense frenzy; said the doctor was so dark he must be the devil, and made two assaults on him and continued destructive. After being treated with restraint and the cold pack she fell into a deep sleep, on awakening from which she was perfectly rational, and recollected nothing that had occurred subsequently to the discovery of the fact that her dress had been spoiled.

It is of peculiar interest to compare this case, a simple, clinical record, with three others in which judicial determination as to criminal responsibility was required.

In a case I was called as alienist the accused was the wife of a saloon-keeper. The victim had an equity in the building where the saloon was. The accused had a neuropathic constitution evinced by the survival of night terrors from childhood. These night terrors were accompanied at times by casual hallucinations of sight and hearing. This psychic disturbance was accentuated with the onset of menstruation and was particularly marked thereafter around the menstrual period. Her early marital life was very happy. She had one child who had reached the age of ten at the time of the homicide. A short time before the homicide the husband formed a liaision with its victim. Shortly before the homicide the accused learned that the husband was to make a trip to the Paris Exposition of 1900 with the woman at the latter's expense. She had saved a few hundred dollars. Putting this money in her stocking she went to her husband's saloon, the evening preceding the homicide, and asked him to take a walk with her. She asked her husband about the Paris trip who told her that the woman wanted him to go and would put up plenty of money to have a good time. She then took the money out of her stocking and offering it to him asked him to stay home. He asked her how much it was. When she told him the amount he laughed at her and said it would be enough to take him to Paris, but not enough to bring him back. He then stated that the other woman was willing to spend thousands, where she had but hundreds. She then returned home alone and had no sleep that night. She was seen at all hours at her window as she had been for many nights before by a policeman on duty. The next morning she purchased a revolver intending as she said to end it all by killing herself. She then went to the saloon to beg the woman to give her husband up. The negro porter went to the foot of a stairway leading into a room behind the saloon and told the victim that the accused's husband wished to see her. She came down the stairs partially clothed. The accused told her who she was and her errand. From this time the accused remembers nothing save a laugh by the woman and her scared expression. The victim was then slain by a pistol shot and the accused taken into custody by a policeman who noticed her dazed appearance. She did not regain perfect consciousness for some hours after the occurrence. She had no conception why she was imprisoned. In spite of much public prejudice against the plea of insanity the jury acquitted the accused, finding that while she was insane at the time of the homicide she was now sane.

In the second case a man of fifty-five who had led a wandering life, quite common with mechanicians in both English- and German-speaking countries, had lived for a time in a somewhat unsettled Pacific Coast region. Here controversies were settled by the revolver. The man who could draw first had the advantage. On one occasion the accused ejected a rowdy from a ladies' dining room in a hotel. The rowdy shot at him through his trousers pocket. This seems to have made a permanent impression on him.

The accused invented and patented several petty labor-saving devices. For the better manufacture and sale of these he removed to Chicago. Here he became acquainted with mechanicians to whom he committed the manufacture of his device. He purchased for them machinery and advanced money

*Read before the Juridical Section of the XVI International Medical Congress, Aug. 29-Sept. 4, 1909.

with the understanding that the machines (a patent drill) were to be made by a certain time. This time was greatly exceeded when he found the people to whom he had advanced money removing their place of business without notice under suspicious circumstances. He made demands for the return of the machines bought and of the money. These demands were evaded, whereupon he called in a lawyer. This lawyer made an appointment for him and the lawyer of the other people as well as the clients of the latter. They all met in an office of the debtor's lawyer. The accused went with a revolver, which he had always carried since his Pacific Coast days, to the meeting. Here an active controversy ensued. During this the accused believed he saw the debtor put his hand in his hip pocket. He then attempted to draw his own revolver. From this time he remembers nothing for twelve hours afterward until he awoke in the police station. During the period immediately after attempting to draw his revolver, he was struck at by a chair and the revolver went off, the ball striking the debtor and inflicting what was thought, at first, to be a fatal wound. The accused then fired the revolver aimlessly. A policeman was called in and conducted him to the station. According to the testimony of the policeman, the testimony of his lawyer, and the antemortem statement, as it was believed, of the man shot, the accused was in a state of hallucinatory confusion with no consciousness of his surroundings. The man shot recovered and then prosecuted the accused very venomously. The jury, under the charge of the judge, taking the scientific ground that it was the state's duty under the circumstances to prove sanity beyond a reasonable doubt, promptly acquitted the accused.

In a third case, in which I was consulted, the accused had been in business with a brother. His maternal uncle was of mental instability and a younger brother had been an inmate of an insane hospital between 15 and 25. The victim of the attempt at homicide was a very tricky individual, given to threats enforced by a revolver. The accused lent money to the firm without proper security. This the elder brother repeatedly refused to account for. Later he agreed to pay back the money in weekly payments. At this time the accused suffered from helmet sensations, ringing in the ears, dizziness, and confusion. The accused accepted notes for the weekly payments endorsed by a mutual business friend. This friend suggested that the firm be incorporated so that the rights of all concerned could be clearly defined. At this time the accused was sleepless and the helmet sensations, ringing in the ears, dizziness, and confusion came more often and lasted longer. The business friend in consequence suggested that the accused go to a watering place and recuperate. While at the watering place the firm was incorporated, but the name of the accused did not appear among the incorporators. The officers of the incorporation were later elected. The elder brother was made president and treasurer, his wife secretary, and the accused vice-president. At the end of the fiscal year the accused asked that the corporation declare a dividend justified by its financial success. This the president refused to do, whereupon the accused threatened to have a receiver appointed. Thereupon the president threatened to have the accused voted out of the corporation. From this time the cerebral symptoms of the accused increased. He was unable to sleep, and walked the streets day and night in a dazed state. He would find himself in different parts of the country where he had gone in these periods of mental confusion, not knowing how he got there. About this period the elder brother threatened the accused with a revolver which he took from the left-hand drawer of his desk. A meeting of the corporation was called, to which the accused took a revolver to protect himself. The details of the meeting are imperfectly remembered by the accused. The elder brother read some paper and when it was finished started to open the drawer in which was the revolver. From this time the accused remembers nothing until he found himself in a patrol wagon an hour after with a policeman. The accused knocked the elder brother off his chair with his revolver soon after the latter opened the drawer. The elder brother rushed at the accused, who was attacked from behind by the former's wife. The elder brother twisted the revolver in the accused's hands discharging it several times. A younger brother smashed the door with a chair and rushed in between the combatants. A policeman was then called and the accused placed under arrest. The accused, after repeated delays by the prosecution, was at length, on his own demand, brought to trial and acquitted on a technicality as to time of trial.

The forensic status of this psychosis must be determined by the clinical evidence in the individual case. So far as brevity, explosiveness, and violence are concerned, it does not stand alone as has repeatedly been claimed by those who employ special pleading in science. To call it cerebral hyperemia when the fact of its occurrence cannot be denied is merely to dodge recognition of the transitory furor which is the essential characteristic of the alleged cerebral hyperemia. To say it must be an expression of larvated epilepsy when the most minute examination fails to discover epilepsy of any nature is likewise special pleading equally unworthy of a scientist. At present it must be admitted, however, that the swing of the pendulum is a little too far in the other direction. While transitory frenzy is psychologically akin to the fugues of epilepsy, still it differs from these in being an isolated phenomenon of a life while the fugues are recurrent phenomena natural to such a pseudorhythmic disorder as epilepsy. Many of the recurrent fugues, said to be non-epileptic, are so designated because of a purely grand-mal conception of epilepsy. The forensic status of transitory frenzy is therefore a matter of fact to be settled by experts in continental countries and by juries in English-speaking countries, and not a matter for judicial dictation. The question of public benefit is one for a legislature, not for a judge.

It has been stated by Fisher (E. D.) of New York that the plea of transitory frenzy is not accepted by the American courts. This is an error, not only as to the United States courts, but as to those of New York State. The jury in the Cole case at first returned with the statement that they found the accused sane a moment before and a moment after the killing, but they were in doubt as to his sanity at the moment of the homicide. The judge told the jury that they must give the prisoner the benefit of any rational doubt founded upon the evidence. Thereupon the jury found the accused "not guilty."

Transitory frenzy must be recognized by any tribunal which admits that irresponsibility exists where freedom of the will is impaired. In States like New York were insanity to be accepted as a

defense must destroy the knowledge of right and wrong, transitory frenzy must be accepted as a defense, since by creating unconsciousness of the act done it emphatically destroys a knowledge of right and wrong. In Illinois it must be received under the test laid down in Hopps vs. the People, that irresponsibility results when the degree of insanity is such as to create an uncontrollable impulse to do the act charged, by overriding the reason and judgment and obliterating the sense of right and wrong as to the particular act done, and to deprive the accused of the power of choosing between them. The plea of transitory frenzy must therefore be received in courts which admit the continental European test of impairment of the will, the late English and American right and wrong knowledge test, and the older English and American uncontrollable test which is in essence that of Continental Europe. The forensic status of transitory frenzy turns upon the evidence whether it has occurred in a particular case.

The determination of its clinical status is easy according to the pre-Kraepelin psychiatry. Kraepelin would place it in what he calls the collapse-deliria. Here he also puts the confusional and stuporous states, which are incongruous, with his classification. This is not so much of a hodge-podge as would first appear. The deliria, the confusional and stuporous states are closely related from the clinicopsychical standpoint. The commoner name of enteric fever shows this. Typhus is the Greek for stupor and typhoid the Greek for stupor-like. The clinical phenomena of the psychic states resulting from exhaustion, from the strain of migraine, multiple neuritis, and neuralgia are very similar to those of transitory frenzy. There is a confused mental state attended at times by violence and destructiveness. Of this, as a rule, the patient on recovery retains no remembrance. The same, of course, is true of mental states which precede, take the place of, or succeed epilepsy. The distinction between transitory frenzy and these states is that it may be and generally is, an isolated phenomenon in a lifetime. The etiological moment usually comes but once. The menstrual period with its mixed soil of toxemia, nervous instability, and exhaustion furnishes psychoses with clinical characteristics resembling those of transitory frenzy. Tabes, with its circulatory disturbances, its renal and hepatic instabilities often presents isolated psychoses differing from transitory frenzy only in the fact that they occur in a tabetic. In migraine, as Kraft-Ebbing has pointed out, similar psychoses may occur which may become recurrent through the rhythmic law of the nervous system or may remain isolated phenomena. In heat exhaustion similar psychoses may occur, which differ from those produced by sunstroke in the fact that they do not result from a basis of morbid suspicion, but destroy consciousness. The same is true of the allied states produced by electricity and traumatism. In both these states, however, confusional explosive psychic states occur which resemble transitory frenzy, but are recurrent phenomena, not isolated. The psychoses which at times replace gout and rheumatism assume all the essential characteristics of transitory frenzy. While generally the recurrent element might be expected in these, still the absence of one of the essential factors of the etiological moment often prevents them from being more than isolated phenomena. The transitory furibund psychoses due to the untoward effect of quinine and other drugs on unstable constitutions are also closely akin to transitory frenzy. Indeed, on one or two occasions in the United States such a plea has led to a refusal to prosecute. From what has been said it is clear that the psychosis, transitory frenzy, belongs in a group of the confusional insanities of toxemias and exhaustion, and is not psychically or pathologically, as has been claimed by the special pleaders, an anomaly.

An unnecessary confusion of the question has resulted from the etiological classifications of Risch and others creating what are called psychogenic states. These include stuporous states with or without active psychomotor excitement, with or without violent behavior. While transitory frenzy may be and often is psychogenic in exciting origin there is, as already pointed out, more to the etiological moment than the simple exciting cause, otherwise it would not be, as it generally is, an isolated phenomenon in the life of the individual. This is so equally true of all the psychogenic states described by Risch that the term becomes by its limitations an absurdity, since necessary predisposing factors are ignored by it.

The transitory frenzy of popular caricatures and of legal denunciation is not the transitory frenzy of science and the law. It lacks every characteristic of the psychosis.

Ovarian Grafts With and Without Anastomosis of Vessels.—Mauclaire believes that in order that ovarian grafts may be successful it is best to provide a blood supply by anastomosing the ovarian vessels with some others, preferably the epigastric. He has had two positive cases in women. There is no doubt that both heterografts and autografts have been successful, both in animals and in women, although not nearly all the grafts have taken, and many have undergone atrophy. The author gives a review of the successful cases recorded. Heterografts and autografts are made for the purpose of avoiding the nervous symptoms that result from double ovarian ablation, especially obesity. Heterografts are also made to render pregnancy possible. Another indication is amenorrhea from congenital ovarian atrophy. If we are to succeed generally the author believes that we must supply nutrition to the graft by furnishing it with a circulatory supply. This appears to be much more important than a continuous nerve supply.—*Archives Générales de Chirurgie.*

Histological Observations in Human Osteomalacia.—Gino Baggio has examined histologically the bones of four victims of osteomalacia, one man, and two women who died of intercurrent affections in advanced life. There were found only islands of calcified bone substance. The osseous trabeculæ were traversed by canals filled with fibrous substance rich in vessels. There were three types of medulla, lymphoid, fibrous, and fatty; of these the fibrous predominated. The bone corpuscles found in the ossified portions showed elongation toward the periphery of the islands, their shape being preserved only at the center. In the uncalcified portions the structure consisted of fibrous tissue in large parallel bundles. The corpuscles in the osteoid zones were large and with dilated, short prolongations. When the process of osteomalacic alteration is in progress the limits between soteoid and calcified tissues are changed continually by a dissolving of the calcerous salts produced by the same cells which formed it.—*Archivio per le Scienze Mediche,* Vol. XXXL., No. 26, 1909.

Congenital Muscular Atony.—Lévi-Sirurgue describes congenital muscular atony as occurring in new-born children, and being distinctly regressive, ending generally in recovery, unless the infant is carried off by some intercurrent respiratory affection. The cause of this affection appears to be a congenital lack of development of the muscles, or of the medullocerebellar nervous strands. The muscles of the infant are soft and flaccid; there is so marked a paresis that the child is unable to make voluntary movements, and later is unable to stand alone or walk. There is no affection of sensibility. The spine is abnormally movable. The tendon reflexes are abolished, and electrical contractility is almost if not quite abolished. Treatment consists of faradism of the muscles, baths, and massage, combined with arsenic and strychnine.—*Gazette des Hôpitaux.*

THE EARLY TREATMENT OF THE INSANE.

IT may be freely granted that the treatment of the insane is now conducted on far more intelligent and rational lines than was the case formerly. In fact, the progress made in this direction has been, during the past few years, remarkable, but there are still features in the treatment of those suffering from mental troubles which are susceptible of improvement. Up to a comparatively recent date, the treatment of insanity in its early stages was more or less conspicuous by its absence. Those alleged to be of unsound mind were neglected until their mental state became too obvious to be overlooked. Of recent years reception wards for this class of patient have been instituted in many hospitals in different parts of the country.

A Royal Commission on the Control and Care of the Feeble Minded in Great Britain which has issued its report recently is very insistent that insanity in its early stages should have more attention than has hitherto been the case. The report of the British Commissioners contains the following statement: "We regard it as very important that a free hand should be allowed to committees in dealing with this matter, so that they may be able to utilize many existing agencies for the purpose. We do not consider it at all necessary that in crowded centers of population large and expensive buildings should be erected like the reception blocks of the great county asylums. Separate wards in workhouses or in general hospitals might be used under contract, or existing houses or other buildings adapted. The special advantages of these reception wards for the clinical study of mental disease are so evident that many general hospitals, especially those to which medical schools are attached, would be glad, we think, if they were subsidized, to provide them within their own premises with medical nursing and attendant staff complete." The Asylums Committee of the London County Council, impelled by the Commission's report, has decided to suggest the reintroduction at the next session of Parliament of the Lunacy Acts Amendment Bill, by which the Council has sought power to establish receiving houses for the accommodation of persons mentally afflicted or alleged to be of unsound mind, with the object, if possible, of curing insanity in its early stages. The scheme proposed by the committee is that the Council shall provide receiving houses to be entirely under its supervision and staffed by its officers, to which an alleged lunatic will be taken. The medical superintendent of the receiving house will have power to detain the alleged lunatic for a period not exceeding three days, but he must bring him before a justice before the expiration of that period or else discharge him. The medical superintendent is to report to the justice whether, in his opinion, the alleged lunatic should be sent to the county asylum or be detained in the receiving house. If the justice decides that the case is one for asylum treatment the usual proceedings under the Lunacy Act will be taken. If, on the other hand, he concludes that the case is one for detention in the receiving house, the justice is to call in the superintendent, and may, if he so wishes, call in any other medical practitioner, and after investigation order the alleged lunatic to be detained in the receiving house. This order remains in force for only six weeks, but extensions not exceeding three weeks at a time may be made by a justice if thought necessary. The patient during his detention in the receiving house will not be designated a lunatic. At any time during the period of detention the medical superintendent, if he thinks that the patient should be removed to an asylum, may bring the patient before a justice with a view to the ordinary reception order being made.

The London committee uses much the same arguments in support of the scheme as have been brought forward from time to time in the MEDICAL RECORD, but as good arguments cannot be recapitulated too frequently, the main points may be run over again. The alleged lunatic, as soon as he enters the receiving house, will be under the care of physicians who have made a specialty of mental disease. The greatest authorities on insanity hold the opinion that the increase of insanity which has been apparent in London, and it can be added in other large cities of the civilized world, during recent years, can be limited only by proper early treatment of cases. Such treatment would be provided in receiving houses, and thus many persons who are at present sent to asylums would not need to go to such institutions at all, but would improve and recover in the receiving houses. In connection with these there could be, if required, an out-patient department, which would enable persons who needed it to obtain advice. By these means it is believed that many cases of incipient mental disease might be arrested, and the necessity for long seclusion in an asylum avoided. The London County Council thinks the matter so urgent that it proposes to establish quickly two receiving houses, each for 250 patients, one on the north and one on the south side of the Thames. In all highly civilized countries, and the more highly civilized the more aptly the remark will apply, insanity is on the increase. Even if, as is sometimes argued, acute dementia or well-established madness is not obviously more prevalent than formerly, at any rate there are more individuals of unstable temperament and who, given favoring conditions, may develop insanity, than there used to be. Unfortunately, in large towns favoring conditions are

always present, and the strain of modern town life so affects a certain large class of persons that there are always candidates for receiving houses. A large proportion of such people are amenable to skillful treatment, and consequently the plea for receiving houses seems to be thoroughly justified.

THE EARLY DIAGNOSIS OF TABES DORSALIS.

The diagnosis of locomotor ataxia in its initial stage is often no easy matter, the detection of the signs and symptoms of the disease requiring careful search, an acute eye, and an alert mind. It is in this stage, however, that the diagnosis is of especial importance, particularly in deciding the question of whether or not a man should marry. Much unnecessary hardship has been caused by physicians in overlooking early cases of tabes dorsalis, and permitting sufferers to marry when in a physical condition which would make matrimony little better than a crime. Every care should be taken in examining a prospective bridegroom, especially if there is the faintest suspicion of a previous specific taint, in order to detect the first suggestion of this insidious disease. In this relation an article by Kann, of Bad Oeynhausen on the diagnosis of initial tabes, which appears in the *Berliner klinische Wochenschrift* for June 21 is of interest, for, while it teaches nothing new, it emphasizes some points which seem worthy of note. The pain in early tabes is often not of the typical lightning character, but may be a dull ache in the joints resembling chronic rheumatism or persistent boring pains in various parts of the body. The well-known paresthesias may be absent from the hands and feet, but present in the perineal region. Digestive symptoms, loss of appetite, or constipation may be early symptoms, while bladder symptoms of all kinds must be investigated with care. The Argyle-Robertson sign may be only partial or unilateral. Inequality of the pupils, loss of the reflex pupil reaction, and double vision from muscular paresis may occur early. The loss of the knee jerk appears comparatively late in the disease, and is of but little value in early diagnosis. The tendo-Achillis reflex, however, disappears much earlier. Owing to their frequent absence in health, the state of the arm reflexes is of little value, though that of the triceps is of some significance, especially if it is weaker on one side than the other. The hypotonicity of the musculature shown by the abnormal motility of the joints is of especial value.

Pronounced ataxia occurs late, but the symptom may manifest itself early by slight uncertainty in the dark or by tremor of the leg when held in the air. When the Romberg symptom appears to be negative, it may be elicited by standing with one foot before the other, or with one off the ground; while in the absence of gross swaying, an abnormally active play of the leg and buttock muscles may put the examiner on his guard. The important point is not the presence of abnormal movements, but their increase on closing the eyes. All abnormalities of sensation should be studied, especially those in the neighborhood of the breasts and perineum. The deep joint sensation is demonstrated by moving the great toe, and its loss is of significance. More recent discoveries of value are the lymphocytosis in the spinal fluid and increase in globulin as shown by Noguchi's test. The Wassermann test, too, may give information of value.

A careful and systematic search for these minor and more obscure symptoms of tabes in every suspect of past syphilis or candidate for matrimony may establish a diagnosis in a case which otherwise would be overlooked, may save the physician some later chagrin and a prospective bride a life of slavery and unhappiness, and by enabling the institution of early treatment will give the patient himself the greatest possible chance for checking the course of the disease.

THE RECOGNITION OF SCIENTIFIC WORK.

If one may judge from the methods pursued by Dr. Wiley and his followers at the Pure Food Convention in Denver last week, it is evident that they knew he had no case. Without doubt he is sincere in the delusion that sodium benzoate is toxic when ingested in minute quantities, but he was extremely unfortunate in his friends and in the methods they adopted in the endeavor to carry the convention against the United States Government. The press, both lay and medical, was bombarded days before the convention met by ready-made telegrams from Denver; editorials were printed in many influential papers seeking to obscure the issue by pretending that the question was one of garbage *versus* pure food; a medical paper reissued, or redistributed, just before the meeting, a three-months-old number filled with platitudes regarding the advantages of clean catsup and jam; and Dr. C. A. L. Reed, a gynecologist, distributed broadcast copies of a paper in which he questioned the personal integrity of four of the best known chemists and laboratory workers of the country, fortifying his inexpert statements with the announcement that he was chairman of the Committee on Legislation of the American Medical Association, thus giving the impression that he spoke officially for the physicians of the country. As a matter of fact, it was published in the press last January that this committee, meeting in Washington, passed a resolution disavowing for the American Medical Association the utterances of Dr. Reed at that time, which he repeated at Denver, regarding the findings of the Referee Board of Consulting Scientific Experts. He is the spokesman neither of the medical men of the country nor of the members of the American Medical Association. In marked contrast with these tactics was the dignified action of the members of the Referee Board appointed by the Government to review the experiments of the chemist of the Department of Agriculture. They addressed the convention, simply telling what they had done and why they had done it, summarizing briefly their experiments, and giving their conclusions and the reasons therefor. Their honesty of purpose was so evident and their reputation as experts was so unassailable that the convention was convinced and endorsed their action by a substantial majority.

This is a defeat for Dr. Wiley in his contention that sodium benzoate in small quantities is injurious, but it is no victory for dishonest manufacturers who want to utilize factory sweepings in the making of catsup and other such delectable food products. Those men know that they can make "garbage" palatable by means of vinegar and spices much better than they can by the use of benzoate of sodium, and so they take little interest in the decision of the Referee Board. This is, however, apart from the issue at Denver, which was solely whether the findings of the Referee Board were correct. Dr. Wiley's experiments, upon which his condemnation of sodium benzoate was based, were crude and unscientific, as was clearly shown by Dr. E. E. Smith in his review of them published in the MEDICAL RECORD of January 2, 1909. The decision of the Referee Board, on the other hand, was based upon the results of three series of experiments, conducted by expert chemists and physiologists, working independently, in New York, New Haven, and Chicago. The findings of these three independent sets of experimenters were substantially the same, and the board was unanimous in its conclusion that "sodium benzoate in small doses (under 0.5 gram per day) mixed with the food is without deleterious or poisonous action and is not injurious to health." This report was signed by Ira Remsen, Russell H. Chittenden, John H. Long, and Christian A. Herter. It would have been strange had the Pure Food Convention not endorsed a report made by such men, and had it not discredited the intemperate accusations of bias and dishonesty brought against them by men trained in the arts of the politician.

As we said above, this vote of the Pure Food Convention supporting the conclusions of the Referee Board is no victory for dishonest food manufacturers. It is simply and purely a vote in support of honest scientific investigation and in repudiation of nonsense uttered by unscientific and inexpert partisans of a chemist who has apparently made a mistake. It is entirely apart from the question whether catsup is more wholesome when preserved by sodium benzoate than when spices are used to prevent its decomposition. This is another matter entirely, and is one which it might be well to submit to the Referee Board for decision.

THE CONVULSIONS OF WHOOPING COUGH.

WHILE pertussis in itself is a serious disease, especially when occurring in early infancy, the fatalities are caused, as a rule, not by the primary condition, but by one or other of its complications. The prognosis of a simple case is certainly good, but the appearance of signs of bronchopneumonia marks the transition of the disease from one of expected recovery to one of serious import, and the onset of convulsions makes the outlook practically hopeless. This latter complication of whooping cough is fortunately rare. Roger found it to occur fifteen times in four hundred and thirty-one cases, while in the Charité Hospital in Berlin it appeared twenty-four times in four hundred and seventy-six cases. When convulsions occur in pertussis, they usually begin from the third to the sixth week of the disease, in children under three years of age, and may be preceded for a few days by headache and restlessness. They may be local, but are more commonly general. Rarely coming singly, they recur more and more frequently, the patients soon becoming comatose between the eclamptic seizures, and dying in a condition closely resembling the status epilepticus. At autopsy the only abnormality found in the cerebrum is a marked edema. In consideration of this edema, Eckert, assistant to Professor Heubner in Berlin, has recently been experimenting with a new method of treatment, the striking results of which he has reported in the *Münchener medizinische Wochenschrift* for August 3, 1909. The four patients treated presented typical cases of pertussis convulsions, varying in age from eleven to seventeen months. They were unconscious, and the eclamptic attacks were recurring with great frequency, in the first case as often as forty-eight times in twenty-four hours. Believing them to be due to the cerebral edema, Eckert performed lumbar puncture, and removed from five to twenty-five cubic centimeters of clear, sterile, cerebrospinal fluid. The intraspinal pressure varied in the different cases from 150 to 330 mm., and in each case dropped after the operation to 80 mm. In two of the cases the convulsions ceased immediately; in one five more occurred and then they stopped; and in the fourth a second puncture was required, after which the convulsions occurred three times and then disappeared. As the operation, though stopping the convulsions, did not clear up the coma, "souse baths" were given. These restored consciousness immediately. The four patients all made uninterrupted recoveries from the whooping cough. As to the theory of the treatment, Eckert believes that the cerebral edema is caused by congestion due to the powerful expiratory spasm of the cough, recurring with sufficient frequency to prevent renewal of the cerebral circulation between the attacks. The lumbar puncture removes enough fluid, not in itself to overcome the edema, but by relieving the intracranial pressure to enable the meninges to absorb the excess of fluid, this being actually brought about by the suction on the veins produced by the violent inspiratory spasm incited by the sudden cold baths. Whether this theory is correct, and it seems at least logical, the results of the treatment were brilliant, and the method offers hope for recovery in a complication of whooping cough which has heretofore been considered to be practically hopeless.

BISMUTH IN THE DIAGNOSIS OF GASTRIC ULCER.

THE differential diagnosis between ulcer of the stomach and a simple gastric neurosis is often a matter of some difficulty, and requiring no small degree of clinical skill, especially in cases in which the ulcer is not accompanied by hemorrhage. The symptoms of pain, vomiting, and point tenderness may occur in both conditions, while the finding of a hyperacidity, though suggestive of ulcer, is far from being pathognomonic, and the other characteristics of a test meal are of little or no aid. In view of the seriousness of the condition of ulcus ventriculi and the necessity of early and rigid treatment, a specific test is much to be desired. In the *Deutsche medizinische Wochenschrift* for August 5, 1909, Karl Grandauer of Berlin has reported some investigation of a procedure which he believes may be of use in the diagnosis of gastric ulcer. He has found that an examination of the contents of a stomach, the lining membrane of which is normal

and the motility not greatly reduced, will show, twelve hours after the administration of bismuth, practically no trace of the drug, whereas, if the mucous membrane is irregular, the black crystals may be present in fairly considerable quantity. His technique consists in giving two grams of bismuth subnitrate at night, on an empty stomach, and the following morning an ordinary test meal. One hour later this is removed in three portions. The first consists of the undiluted contents; the second is all that can be removed with 100 c.c. of wash water; and the third comprises the wash water required to clean the organ thoroughly. The first is used for the usual chemical and microscopic examination. The second and third are allowed to sediment, and a few drops are removed from the bottom with a pipette and examined microscopically for bismuth. Grandauer finds that in cases of pure gastric neuroses practically no bismuth can be demonstrated, while in cases of ulcer, cancer, and erosions it is found with ease in the wash water, owing to its retention in the crevices of the mucous membrane. The test is also positive in cases of gastritis, due to the bismuth being held by the mucus. He concludes that in the absence of motor insufficiency, carcinoma, and gastritis, the finding of bismuth in any quantity is a diagnostic sign of ulcer.

Intoxication with Magnesium Sulphate.

That a drug so extensively used as magnesium sulphate, on lay initiative as well as on professional recommendation, should occasionally give rise to toxic effects, at times even of a fatal character, and altogether apart from excessive dosage or adulteration, emphasizes a danger that may occasionally be encountered in connection with any efficient therapeutic agent. A case in which such an untoward result was observed was recently reported by Dr. Charles Fraser in the *Lancet,* recovery ensuing after exceedingly alarming symptoms. Four of the five other cases that could be found recorded in the literature terminated fatally. A boy, 3½ years old, apparently in perfect health, took by mistake for sugar a heaping teaspoonful of magnesium sulphate, about half an ounce by weight, and washed it down with a mouthful of milk. Retching soon set in, with considerable pain in the stomach, and later nausea and vomiting. The bowels remained unmoved, and thirst was marked. The face became pinched, the eyes sunken, and the skin pale. Only a small amount of urine was passed. The abdomen became distended and rigid, and the skin markedly hyperesthetic. The temperature was but slightly elevated, while the pulse was considerably accelerated. Acute peritonitis being suspected, the abdomen was opened, and two pints of blood-stained serum, evacuated. This was on bacteriological examination found sterile. No other abnormality was discovered. For a while the outcome of the case appeared dubious, but in the second twenty-four hours after operation improvement set in and went on to complete recovery. It is pointed out that the symptoms observed may have been due to intussusception or volvulus, but of the presence of either of these conditions there was no convincing evidence. No adequate explanation is at hand for the symptoms noted in the six recorded fatal cases. In some it may have been the result of exhaustion from excessive purgation, in others of some form of intestinal obstruction, and in yet others of the directly toxic effect of the magnesium sulphate.

The Budapest Congress.

The Sixteenth International Medical Congress, which has been held during the present week in the beautiful capital of Hungary, will no doubt go down to medical history as one of the most enjoyable, if not the most numerously attended, of any similar gathering. Yet the attendance must have reached no mean figures, for, as noted in our special cable report, there was a registration of practically 2,000 foreign delegates, and this added to the number of native physicians present, doubtless brought the total up to, if not exceeding, 5,000. Although no sensational discovery was announced, at least during the first half of the meeting covered by our report, if the papers and addresses, four of which we are privileged to present to our readers this week, are an indication, the general average of the work done was sufficient to make the Congress a notable one. A feature of interest to Americans was the decoration of the statue of Washington, which the liberty-loving Hungarians had erected in his honor in their capital. The American delegates attended this celebration in a body, and Count Apponyi, the Hungarian Minister of Public Instruction, honored the occasion with an address and brought the school children under his care to grace it with the singing of patriotic airs. The social festivities, as was inevitable when such a hospitable folk as the Hungarians were hosts, were most enjoyable. Altogether, the Budapest Congress will be voted a success, and those who have had the good fortune to be present will cherish the occasion as one full of pleasant recollections.

News of the Week.

Civil Service Examinations.—The New York State Civil Service Commission will hold examinations on September 18, 1909, for the following positions: Assistant Sanitary Chemist, Department of Health, $1,200 to $1,500; Physician, Homeopathic, and Physician, Regular, $900 to $1,200, and Superintendent or Assistant Superintendent of State Hospital Training School, $900 to $1,200, and maintenance. The last day for filing applications for these positions is September 11, at noon. For information and application for any of these examinations, address (postal card preferred) State Civil Service Commission, Albany, N. Y.

More Pure Milk Depots.—A plan calling for an expenditure of $55,850 during the next year to reduce infant mortality in New York City by supplying pure milk and educating tenement mothers has just been made public by the New York Milk Committee in a pamphlet outlining the proposed work for next year. Two new depots are to be opened in addition to the seven now running.

Cholera in Europe.—Asiatic cholera has made its appearance in Rotterdam. On August 26 four deaths were reported, nine cases of cholera were under treatment in the hospital, and forty-two in the observation ward. The Marine Hospital Service in Washington has received a cablegram from the American Consul at Rotterdam, that the Dutch ship *Andyk* sailed from that port on August 25 for Baltimore with cholera on board. Assistant Surgeon Robert A. C. Wollenburg, now stationed at Naples, has been ordered to proceed to Rotterdam to assist the American Consul in seeing that the sanitary regulations required by our government

for ships sailing to American ports are properly carried out. The steamer *Singapore* arrived at Antwerp from Riga with five of her crew dead, presumably from cholera. The ship was quarantined. The epidemic in St. Petersburg continues. Twenty-nine new cases and twelve deaths were reported one day last week. On August 27 one of the officers of the Guard in the Winter Palace was attacked by cholera. The entire staff of officials and servants of the palace is being closely watched. Twelve cases were reported from Riga, with nine deaths during the three days from August 26 to 28. Whereas the epidemic is apparently less severe in St. Petersburg, it is spreading rapidly to the different cities of Russia.

Smallpox in Spain.—Reports from Madrid state that a severe epidemic of smallpox prevails there at present. Compulsory vaccination is being carried out. Considerable excitement was created last week on the steamship *Carpathia* by the discovery that a cabin passenger who had boarded at Gibraltar was suffering from the disease. The patient was isolated, and on arrival at New York was transferred to the Willard Parker Hospital.

Poliomyelitis in Greater New York.—A severe epidemic of anterior poliomyelitis is at present prevalent in the Brownsville section of Brooklyn. It is stated unofficially that during the past three weeks two hundred children have become affected with the disease. That the epidemic is not confined to Brooklyn, but is spreading to Manhattan as well, is shown by the report from Hospital for Ruptured and Crippled, where twenty new cases have been admitted within two weeks. Dr. Terriberry of the staff of this hospital is taking active steps to organize the hospitals and research laboratories of the city in preparation for an acute epidemic of the disease.

A peculiar epidemic in Utah is said to be puzzling the physicians of that State, numerous cases of the disease having appeared there. The fever often rises to 105 degrees, and in many cases the results have been fatal. On the theory that the infection is contracted from handling goats the disease has been called "goat fever." The disease prevails in the goat raising districts, and seems to occur especially at about the kidding time. As yet the investigations of the bacteriologist of the Utah Board of Health have failed to throw light on the cause of the disease.

Bubonic Plague in Hawaii.—Three cases of bubonic plague and one death from the disease were reported on August 23 from the Island of Hawaii. No cases have occurred in Honolulu.

Pellagra.—Five deaths from pellagra are reported in Butler county, Alabama, three persons are dying, and five more are under observation. The State Department of Health is investigating the conditions in Clark county, where more than one hundred cases are reported. Captain J. F. Siler of the Army Medical Corps has been sent to Peoria, Ill., to investigate and report upon an outbreak of the disease there. About 75 cases have been found among the 2,200 inmates of the Peoria State Hospital. This is the first outbreak of the disease that has been reported in the United States north of Mason and Dixon's line. Dr. James A. Egan, Secretary of the Illinois State Board of Health, has been investigating the cases with Captain Siler and states his belief that the disease did not originate in the institution, but that all the patients had pellagra when they were received and that their insanity was but a symptom of the disease.

Two Epidemics of Anthrax.—Three large dairies in Chenango county, New York, are affected with anthrax. Six of the cattle died on August 27. Chenango is in the heart of the district that ships many thousands of pounds of milk to New York and other Eastern points every day. An outbreak of anthrax in the dairy herd at the farm of the University of Wisconsin developed recently. The authorities of the College of Agriculture have taken every precaution to check the disease and to prevent its further spread. The death of a cow in a pasture aroused suspicion. The sale of milk was discontinued and the dairy herd was placed under strict surveillance. A quarantine was established and an isolated stable provided to which all cows that showed abnormal temperatures were taken.

The Nelson Morris Memorial Institute for Medical Research.—Chicago is to have an institution for medical research similar to that founded in New York by Mr. Rockefeller. The new institution is the gift of Mrs. Nelson Morris, and $250,000, which is needed for erection and furnishing, has been given by her as a memorial to her husband. The institution will be known as the Nelson Morris Memorial Institute of Medical Research, and will be connected with the Michael Reese Hospital. The building will be constructed according to the ideas of Dr. James W. Jobling, Chief Pathologist of the Michael Reese Hospital, who is to be the Director of the new Institute. Dr. Jobling was for a number of years connected with the government laboratory in Manila, and for the last few years has been on the staff of the Rockefeller Institute. The new director is known as the coworker with Dr. Flexner in the discovery and production of the antimeningococcus serum.

Charitable Bequests.—By the will of the late Michael Horn of New York, among many other bequests, the Mt. Sinai Hospital received $5,000, and the Montefiore Home $2,500 to endow memorial beds.

Osteopathy Legalized in Alabama.—Governor Brown of Alabama has signed a bill permitting the licensing of osteopaths. The bill was vigorously opposed, but passed the General Assembly by a large majority in both houses.

New York University Additions.—Plans have been filed for the construction of a new building to be erected for the New York University Medical School. It will be six stories in height, and will adjoin the Carnegie Laboratory. It will serve as a surgical pavilion.

Appointments.—Dr. Paul Gerhardt Wooley has been appointed Professor of Pathology of the Medical College of Cincinnati University and Pathologist to the City Hospital. Dr. Wooley was associated with the Pathological Laboratory of the U. S. Government Hospital in Manila, and more recently has acted as medical adviser to the King of Siam. Dr. William B. Wherry has been appointed Assistant Professor of Bacteriology at the Ohio-Miami Medical College of the University of Cincinnati. Dr. Wherry was also connected with the laboratory of the Government Hospital in Manila. He is now bacteriologist to the Marine Hospital Service in Oakland, and has been in charge of the laboratory work of the Bubonic Plague Commission.

The Physicians National Board of Regents has

recently been formed with offices at 1717 Chestnut Street, Philadelphia. The following are the officers: *President,* Dr. Eugene Underhill; *Secretary,* Jacob R. Jordan, and *Treasurer,* Edwin H. Frazier. The official journal of the board, *The Guide Book,* is under the editorship of Dr. Henry Beates, Jr., *Consulting Editor;* Dr. W. A. Newman Dorland, *Associate Editor,* and Dr. Underhill, *Editor.* The purpose of the organization is to insure the proper subordination of the nursing to the medical profession. It will classify and list "all nurses who are willing to pledge themselves to abide by the instructions of the attending physicians."

Medical Society of the Missouri Valley.—As previously announced, the twenty-first annual meeting of this association will be held in Council Bluffs, Iowa, on Thursday and Friday, September 9 and 10. The features of the evening session will be the President's address, by Dr. C. B. Hardin of Kansas City; the oration on Medicine by Dr. Alfred C. Croftan, and the Surgical oration by Dr. John E. Summers. Dr. Crofton has chosen as his topic, "The Diseases of Metabolism as a Group," and Dr. Summers will discuss "Cancer as a Constitutional Disease; Its Rational Treatment." Programs will be issued August 30, copies of which the secretary will furnish on request.

Surgeon's Heroic Death.—The preliminary report to the Navy Department over the loss of the naval tug, Nezinscot, on August 11, describes the death of acting assistant Surgeon C. E. Trotter. It seems that Dr. Trotter was clinging for over an hour to a piece of wreckage and had become greatly exhausted. Just as a boat, then overloaded and in a heavy sea, came to his rescue, he saw a sailor at a short distance in much distress in the water and told the rescuers that he was all right, for them to get the other man. This act of self-sacrifice cost Dr. Trotter his life.

Obituary Notes.—Dr. William Palmer Wesselhoeft of Boston died at his summer home at York Harbor, Me., August 24, 1909, aged 74 years. Dr. Wesselhoeft was a graduate of the University of Leipsig and of the Harvard Medical School, having received his degree from the latter in 1856. He had practised medicine in Boston for over fifty years.

Dr. Paul Randall Abell of Norwich, N. Y., died at his home August 23, 1909, aged 31 years. He was a graduate of the Long Island College Hospital in 1902, and was a member of the Susquehanna Valley Medical Society.

Dr. Homer Bushnell of North Adams, Mass., died at his summer home in Pownal, Vt., on August 23, 1909, aged 63 years. Dr. Bushnell received his medical degree from the University of Michigan in 1873. He was a member of the Berkshire County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. William H. Wells of Sacramento, Cal., died on August 15, aged 91 years. Dr. Wells was one of the oldest physicians in California, where he went in 1849. He was a native of Connecticut and a graduate of the Rush Medical College. He practised for many years at Silveyville, Solano County, California.

Dr. Walter A. Smith of San Francisco, Cal., died of pneumonia at St. Francis Hospital, in that city, on August 14, 1909, aged 30 years. He was a graduate of the Cooper Medical College in 1907 and was resident physician to St. Francis Hospital.

Dr. Harmon W. Gross of Quincy, Mass., died suddenly on August 24, 1909. He was a graduate of the medical department of the University of Pennsylvania in 1895, and had been on the staff of the Boston City Hospital, the Boston Children's Hospital, and the Massachusetts General Hospital. At the time of his death Dr. Gross was superintendent of the Holy Cross Hospital, connected with the Fore River Shipbuilding Works at Quincy and was a member of the Norfolk County and Massachusetts Medical Societies. In 1906 he was a member of the Quincy Council.

Dr. Thomas S. P. Fitch of East Orange, N. J., died August 24, 1909, at Portland, Maine, aged 64 years. He was a graduate of the Bellevue Hospital Medical College in 1867. Dr. Fitch practised for a few years in New York City and then moved to East Orange. He was a member of the Essex County Medical Society, the Medical Society of New Jersey, and the American Medical Association. For three years Dr. Fitch was a member of the Orange Board of Education.

Dr. G. Colburn Clement of Haverhill, Mass., died at his home on August 27, 1909, aged 54 years, as the result of a cerebral hemorrhage. He was a graduate of Dartmouth College and of the Harvard Medical School in the class of 1880, since which time he has practised in Haverhill, paying especial attention to surgery and ophthalmology. Dr. Clement was a member of the Essex County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. James M. H. Borglum of Omaha, Neb., died suddenly at his home on August 29, 1909. He was a graduate of the Homeopathic Medical College of Missouri in 1874 and a member of Douglas County Medical Society, the Nebraska State Medical Association, and the American Medical Association.

Dr. Elmer D. North of Lansing, Mich., was found dead in his rooms on August 17, 1909. The death was apparently from heart disease and had occurred several days before the body was found. Dr. North was 68 years of age and a graduate of the Detroit Medical College in 1881.

Dr. William Francis Swalen, born in New York City, June 2, 1837, died from apoplexy in his summer home on Shelter Island. He received his medical degree from the Columbia University in 1859 and soon went to the front in the Civil War as assistant surgeon. He was captured at Bull Run, but paroled as a non-combatant and sent to Libby Prison. After being exchanged he was mustered out, but remained an inspector of hospitals for the Sanitary Commission until the close of the war. He was surgeon to the Eye and Ear Infirmary for thirty years. Another step in his career led him into the militia as medical director of the second brigade as well as afterward surgeon general of the state. He is survived by a widow and a stepson. His funeral was held from the Universalist Church of Our Father, August 29, and was attended by many friends saddened by the thought that his life was ended, even though he had exceeded the Psalmist's allotted span by more than two years.

Dr. Charles W. Crispell of Kingston, N. Y., died suddenly at his summer home at Shelter Island on August 30. He was a graduate of the Vermont Medical College in the class of 1883. He was well known as a bacteriologist and was connected with the pathological laboratory at Albany. He was a member of the Medical Society of the State of New York and of the American Medical Association.

Sixteenth International Medical Congress.

(Special Cable Report to the Medical Record.)

Budapest, September 1.—The inaugural session of the Sixteenth International Medical Congress was held on Sunday, August 28, in the Municipal Building. After the singing of the Hungarian national hymn by a chorus accompanied by the Royal Hungarian Band, the Archduke Joseph, representing the Emperor, with a few words of cordial welcome, declared the Congress open. On motion, a telegram was sent to the Emperor thanking him on behalf of the delegates for graciously accepting the patronage of the Congress.

The President of the Congress, Dr. C. Müller, being ill, his address was read by the general secretary, Professor Emil de Grósz. In this address Dr. Müller presented a brief historical review of the successive international medical congresses beginning with that held in Paris in 1867. The idea of a gathering of medical men from the entire civilized world originated at the annual meeting of the French Société de Médecine in Bordeaux in 1865. It was suggested that, as many foreign medical men would probably visit the international exhibition to be held in Paris in 1867, the occasion would be opportune to gather them together for a discussion of matters of universal interest. The Congress comprised 333 French and 589 foreign members. In his opening address the President, M. Bouillaud, said: "We celebrate to-day a great fête, than which the history of medicine can cite no greater." Among the questions discussed were: Tuberculosis in different countries, and its influence on mortality; the possibility of proposing efficacious measures for the restriction of venereal diseases; the influence of alimentation, climate, race, and conditions of life in different countries, upon disease. During one of the sessions, Dr. Pantaleoni, a delegate from Italy, expressed the wish that this international meeting of physicians might be the first of a long series, thus originating the idea of periodical international medical congresses.

The Second Congress was held at Florence, the then capital of Italy, from September 23 to October 2, 1869. Seven questions were discussed, among which were: Marsh miasm, the conditions favoring its developments, its effects, and the most efficient methods for combating it; the therapeutics of cancer; the treatment of gunshot wounds; the hygienic conditions of hospitals; the conditions favoring epidemics in large cities, and the means for prevention; the rights and duties of physicians in regard to legislation in different countries, and the ameliorations which can reasonably be expected therefrom.

The Third Congress was delayed four years, in order to hold it at the time of the Vienna Exposition of 1873. All the questions for general discussion at this meeting related to hygiene. The establishment of quarantine by land and river, and the maintenance of sea quarantine were favored, and the Congress suggested the formation of an international commission for the investigation of the cholera virus. Compulsory vaccination was also recommended to the European governments.

The Fourth Congress was held from September 19 to 25, 1875, at Brussels, under the presidency of Dr. J. F. Vlemingkx. In this Congress various sections were organized for the discussion of subjects belonging to the special branches of medical science. At this Congress the first exposition of drugs, instruments, and other appliances was held, and for the first time also there were a number of delegates from the governments of the various countries. The principal topics of discussion were the prevention of cholera, the rôle of alcohol as a therapeutic agent, surgical anesthesia, the organization of the public hygiene service, and the disposition of the criminal and dangerous insane.

The Fifth Congress took place at Geneva from September 9 to 15, 1877. The membership was less than 500. Prof. Carl Vogt was elected president. Professor Bouchard read a paper on the etiology of typhoid fever, calling attention to its dissemination by water. Broadbent discussed cerebral localization. Esmarch discussed the advantages and disadvantages of his well-known bloodless method of operating.

The Sixth Congress took place at Amsterdam from September 7 to 13, 1879. The membership was under 500. This Congress was marked by Lister's discourse on his antiseptic method of handling wounds, and also by Virchow's address upon the preliminary education of physicians. Professor Donders, the President of the Congress, spoke on the condition of medical science, and emphasized the importance of experimental physiology to its future growth. Sayre of New York gave a demonstration of the value of his plaster-of-paris jacket in spinal diseases. Hydrotherapy in fevers was discussed, and Bright's disease was discussed at length, Semmola contending that the disease is general, and only secondarily local, that the action of moist cold checks the respiratory function of the skin, whence result changes in metabolism and finally changes in the kidney.

The Seventh Congress, held at London, from August 3 to 9, 1881, had a membership of 3,182, and was of all the congresses up to that time the most successful. The Lord Mayor's dinner at the Mansion House, the soirée at the Guildhall, and the conversazione given by the English members at South Kensington were the chief social functions. By a large majority, the committee decided to limit the invitations to the Congress to men, which brought out a protest from forty-three duly qualified medical women. Pasteur reported upon his investigations of chicken cholera, and upon protective inoculation against splenic fever. Virchow spoke on vivisection as an indispensable aid in research, and made a powerful plea for perfect freedom of investigation, showing conclusively that our present knowledge of life is the result of experimentation, and that the only reliable and practical method for the increase of that knowledge is also experimentation. Professor Huxley gave an address upon the relation of the biological sciences to medicine.

The Eighth Congress was held at Copenhagen, from August 10 to 16, 1884. The attendance was over 1,700. Professor Panum of Copenhagen was the President. Pasteur described the results of his protective inoculation of dogs against rabies. Sir William Gull of London advocated international collective investigation of disease. Antiseptic methods came in for a full discussion, which was opened in the absence of Lister, by Esmarch. Virchow spoke on metaplasia. Sayre demonstrated again his plaster-of-paris jacket. Tommaso Crudeli exhibited specimens of malarial blood showing anilin-stained inclusions in the red blood cells, which he regarded as the germs of the disease. McEwen described his operation for genu valgum

The Ninth Congress was held in September, 1887, at Washington. The attendance of foreign members was, because of the distance, and for other reasons, small. The Congress was opened by President Cleveland, and Dr. N. S. Davis was elected president. Compared with other Congresses the principal distinctive features of the medical work were the large number of papers, their almost exclusively "practical" character, and the large number taking part in the discussions. Professor Körösi read an address on vaccination, and showed that compulsory vaccination in the United States might be expected to save 120,000 lives, with a debit of 300 infant deaths as the result of the operation. Dr. W. H. Welch spoke on the effects of vaccination during the incubation period of smallpox. Dr. August Martin delivered an address describing his vaginal operation of total extirpation of the uterus for cancer.

The Tenth Congress, held at Berlin, from August 4 to 9, 1890, was successful, as regards both numbers and scientific work. Some 7,000 members were registered. Virchow was unanimously elected president. The principal feature of the Congress was the address of Koch, in which he announced that he had succeeded in immunizing guinea-pigs against tuberculosis, and also in arresting the growth and multiplication of the tubercle bacillus after inoculation. Lister reviewed the theories of immunity, dwelling on Metchnikoff's theory of phagocytosis, and expressed himself a firm believer in antisepsis as against asepsis. Professor Bouchard propounded a theory explanatory of immunity and infection. Professor von Bergmann gave an address on his aseptic methods, and Billroth presented his statistics, for the ten years under antiseptic methods, of the results obtained in resection of the stomach and intestines.

The Eleventh Congress was held at Rome, from March 29 to April 5, 1894. Professor Giulio Baccelli was president. Over 7,600 members were registered. Virchow, Babès, Michael Foster, Laache, and Jacobi delivered addresses.

The Twelfth Congress was held from August 19 to 26, 1897, at Moscow. To commemorate the meeting the city of Moscow founded a research prize of $1,000 for the congresses in perpetuity. The membership of the Congress was about 7,300. At this meeting Virchow reaffirmed his belief that the grand truth of unbroken cellular succession would never be overthrown. The diagnostic and therapeutic value of serums was discussed. The first Moscow prize was awarded to M. Henri Dunant for his organization of the International Red Cross Society.

The Thirteenth Congress held at Paris, from August 2 to 7, 1900, had a membership of over 6,000. Professor Lannelongue was elected president. At the opening session in the Salles des Fêtes Lannelongue's address emphasized the value of international medical congresses in promoting international intercourse, breaking down prejudice, and cementing the bonds of a common humanity. Virchow spoke on traumatism and infection. Pavlov presented a paper on experimental therapy as a new and extremely fecund method of physiological research. Jacobi of New York spoke on medicine and physicians in the United States. Ehrlich spoke on his theory of the action of toxins. The Moscow prize was awarded to Professor Ramón y Cajal for his great work on the nervous elements.

The Fourteenth Congress was held in Madrid, April 23 to 30, 1903, under the patronage of King Alfonso and the Queen Mother. Professor Calleja y Sanchez was president. The subject of his address at the inaugural session was "The Progress of Medical Science." The attendance at this Congress was over 5,000. The general addresses were by Arthur Thomson on anthropology, Coni in the campaign against tuberculosis in Latin America, Waldeyer on phylogenetic theories and Darwinism, Laache on reciprocity in pathology, Maragliano on immunization against tuberculosis, Brouardel on food adulteration, Fernandez on ocular affection in the tropics, Carracido on polypharmacy, Ramón y Cajal on the plan and construction of the thalamus, and Rolin on prophylactic and therapeutic indications in tuberculosis. The Moscow prize was warded to Professor Metchnikoff, and the Paris prize to Professor Grassi.

The Fifteenth Congress was held in Lisbon, April 19-26, 1906, under the presidency of Professor Costa Alemão, who reviewed in his address the rapid strides that medicine had made since the Madrid Congress three years before. Brissaud delivered an address on infantilism, Hansemann on the significance of domestication of animals in relation to disease, Crocq on the mechanism of the reflexes, and Senn on cancer.

At the close of the address Professor Grósz presented the statistics of registration of the present Congress. There were 1,994 foreign members, of which number 202 were Americans, 235 Austrians, 288 Germans, 92 British, 228 Russians, 281 French, other countries being represented by smaller numbers. In no previous congress had there been such a large representation from distant countries as in this, and this he regarded as an omen of great promise, for the greatest need of humanity to-day was that of the pacific conciliatory force of science; he quoted Pasteur that the realm of science knows no political boundaries, but embraces the whole of humanity.

The report of the secretary was followed by addresses of welcome by Count Apponyi and by M. de Fulepp, the Mayor of Budapest, and then the presidents of the various national delegations made the customary brief addresses of mutual congratulation and compliment. Dr. John H. Musser of Philadelphia spoke in behalf of the American delegates.

In the evening a largely attended soirée of welcome was given in the handsome Gallery of Fine Arts in the City Park. There was music by the royal band during the evening and refreshments were served. The presidents of the twenty-one sections into which the Congress is divided received the members of their own sections, each in a separate room of the gallery.

On Monday, August 30, a meeting was held of Esperanto enthusiasts, who discussed the question of the adoption of their method of intercommunication as an official tongue by the Congress. In the afternoon the American members visited the statue of Washington and placed wreaths at its base. The statue was draped with American and Hungarian flags, and the addresses were interspersed with excellent chorus singing by the school children of Budapest. An address was delivered by Dr. L. C. McMurtrie of Louisville, and Count Apponyi, Minister of Public Instruction, gave a warm appreciation of democracy and of the impulse given by the great western nation to the freedom of humanity.

At the general session Professor Guido Baccelli

of Rome delivered an address on the "Introduction of Heroic Remedies by Open Veins." He said that in syphilis he had had most marvelous results from the intravenous injection of corrosive sublimate, and also in malaria the intravenous injection of quinine was the most efficacious means of reaching and destroying the parasites of the red blood corpuscles. The bacteria which had invaded the cerebrospinal tissues were also most readily acted upon by remedies introduced directly into the blood channels. In tuberculosis, unfortunately, it is not possible to get at the bacilli through the blood stream since the way is blocked thereto by the tubercles.

In the evening the municipality gave a banquet followed by a musicale and reception in honor of the foreign delegates. These functions were largely attended and were pronounced most enjoyable despite the heat, which was intense, even for the American delegates.

At the general session held August 31, Dr. E. F. Bashford of London, Director of the Imperial Cancer Research Fund, delivered an address on cancer [see page 381]. Dr. R. Kutner of Berlin delivered an address in which he advocated the formation of a number of specially equipped centers for post-graduate instruction for medical practitioners, and a scheme was evolved by which such instruction could be made available by all physicians in town or country.

In the evening a reception was given to the ladies of the Congress by Count and Countess Szechenyi on an island in the Danube.

The Congress has awarded the Moscow prize to Professor Bordet of Ghent, and the Paris prize to Professor Hertwig of Berlin.

Correspondence.

PROFESSOR BRIEGER IS HAPPILY ALIVE.

To the Editor of the Medical Record:

Sir:—I am glad to notify you that the information upon which my notice of Professor Brieger's death was based proves incorrect. I received a communication from him yesterday, written in Carlsbad, and informing me that he was about to deliver an address there on the cachexia reaction in carcinoma and diabetes. It is a rare privilege to enjoy one's own obituary and to discover, as Mark Twain once cabled, that "the reports of my death are greatly exaggerated."

August 31, 1909. S. Baruch, M.D.

THE PASSING OF SECTARIANISM.

To the Editor of the Medical Record:

Sir:—The rapid approach of professional unity and higher standards of excellence cannot be better illustrated than by referring to certain recent changes in the names and methods of some sectarian colleges. An old and at one time prosperous eclectic college in Chicago has dropped its sectarian name and teaching. A homeopathic college in Denver and one in Baltimore have in effect taken themselves out of the homeopathic ranks. An old homeopathic college in St. Louis has closed its doors. The board of regents of the University of Minnesota has practically abolished homeopathy in that institution. It is said that some of the Iowa authorities are growing impatient over the burdensome homeopathic department in that university. There remain some three or four strong and well-equipped homeopathic colleges, which are largely reduced to a modern basis, but which remain nominally sectarian. The greatly increased cost of conducting institutions of learning will necessarily close the doors of the smaller struggling colleges, some of which have but a handful of students. The necessity for a division in the medical profession no longer exists, a broad spirit having followed in the train of the immense strides recorded by modern medical science. The prevention of typhoid fever is considerably more interesting than a discussion of the teachings of Hahnemann.

One feature of the situation deserves mention. A progressive old physician, nominally a homeopath, was invited by me to become a member of the regular societies. He replied: "No, I am too old to make new friends. My son is a regular and I am glad of it. Each of us has walked by his best lights. Something had to be done to bring the Old School to its senses. Organized Homeopathy helped to do it. We have not lived in vain, although I am glad to see an end of sectarianism." Medicus.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BARNATO TRUST FOR CANCER—LUNACY REPORT—ENTERTAINMENTS FOR HOSPITALS—AUSTRALIAN TROPICAL SCHOOL—OBITUARY.

London, August 13, 1909.

The topic of this week, both within and without the profession, has been cancer. The announcement that the trustees of the late Mr. H. Barnato had decided to devote his munificent bequest to the building and endowment of an institution for the reception of cancer patients has put aside other subjects of conversation, including to no small degree acrimonious political discussion. You may remember that Mr. Barnato left £250,000 in memory of his brother and nephew, who both predeceased him. This sum was for founding a charity in the nature of a hospital or kindred institution. The trustees were to have absolute discretion as to the application of the fund and the equipment, endowment, and management of the institution. Mr. Barnato died last November and his will was proved in January, since which the trustees have been studying various means of carrying out the intention. At length they have determined on devoting the whole fund to a hospital for cancer patients and have acquired a site adjoining the Middlesex Hospital, in conjunction with which it will be carried on. You know that the Middlesex Hospital has long been a center of cancer research. For 117 years there has been a cancer ward, which was begun by an anonymous donor, afterward found to be Mr. S. Whitbread, M.P. This ward gradually increased until a separate wing was built. In 1900 a research department was instituted by the hospital and everyone interested in such work knows about its investigations. The medical staff of the Middlesex and its laboratories will no doubt have the opportunity of partaking in the extension of such work, though others may have to be added, for it is probable that the new hospital will provide for the comfort of at least fifty patients and in connection therewith a thoroughly equipped research department.

The decision of the trustees has met with warm approval in most circles, though there are suggestions of doubt in some respecting the desirability of increasing the number of separate hospitals. So far as the comfort of patients and the alleviation, the public seems satisfied, but many doctors are impressed with wider views. In all our great hospitals a number of beds are constantly occupied by cancer patients. There are many others who cannot obtain admission and the selection is made in accordance with the prospect of benefit. At present the hope of correcting the disease lies in early recognition and consequent early operation. For inoperable cases an increase in the number of hospitals may be considered as a good use of charitable funds. But for cases with any prospect of cure it is held by many that their distribution among existing hospitals must be better than anything approaching a concentration in one large institution. All the great hospitals are well equipped and their surgeons have experience and skill. The clinical study of cancer and the instruction of students are points which must not be forgotten.

On the other hand, it may be said that there is considerable provision for hopeless cases and it is not impossible that the study of these may lead to important results. There is a cancer hospital in Fulham Road which has 110 beds, and I am informed that the claims of this for help were put before the Barnato trustees, as were those of numerous charities of all kinds.

Mr. Howell Evans, Hunterian professor at the Royal College of Surgeons, is on the staff of this hospital and

says the clinical investigations carried on there are most complete and the pathological museum valuable. Two or three years ago the staff of this hospital desired to convert it into a national hospital for cancer, but the funds were not forthcoming. Another member of the staff remarked that all research helps clinical work and the more money given to either department the greater the prospects of even incurable cases.

Mr. Pearce Gould, as senior surgeon to the Middlesex Hospital, has abundant experience of the working of the cancer department. He is sure its increase will not be in excess of the demand. It provides a home for victims of cancer who are not at the time suitable subjects for surgical treatment, and no limit is placed on the length of their residence while they suffer from this disease. He evidently thinks that almost every patient admitted derives benefit, often very great benefit. One may cherish such an opinion, for a hospital ward with skilled medical supervision and nursing may well give greater relief than a home, even when there is no prospect of radical treatment. On this ground alone a quarter of a million sterling must prove a benefit to these sufferers. If it does as much for science as for philanthropy, its value cannot be exaggerated.

The Imperial Cancer Research Fund is only seven years old, but its scientific investigations are known throughout the world. Dr. E. F. Bashford is the director of the laboratory on the Thames Embankment and superintendent of the whole work. He is about to leave to take part in the international congress at Budapest and will no doubt give an account of what the fund has done at that assembly. I will therefore only mention some points. It was pointed out at the recent annual meeting at Marlborough House, about which I wrote to you at the time, that the work had caused a great change in the views held of cancer, e.g. it has been shown that practically all races are liable to the disease, and that the notion which had prevailed as to the exemption of the Japanese has no foundation; that climate, soil, diet, etc., have not the importance formerly ascribed to such influences; that all vertebrate animals, wild as well as tame, are liable to it, even fish in their natural state in the North Sea and off the coast of Newfoundland. Further, the investigations have not only corroborated the old belief that cancer was a disease of advancing age, but have shown that this is so in all animals, however short or long their lives may respectively be. It is the later period of life in which cancer appears. It has also been proved that the only way of transmitting the disease from one animal to another is by inoculation, and so the nightmare of inheriting it has been dispelled. From extensive breeding experiments strains of mice have been obtained from cancerous ancestors and out of many thousands not a single one has shown inheritance. On the other hand, some old opinions seem to have been confirmed—such as the influence of chronic irritation, which indeed seems to have acquired greater importance with regard to prevention as well as to surgical removal.

Yesterday the annual report of the Lunacy Commissioners was issued as a bluebook. It is made up to January 1 last and shows an increase of certified cases over those of the previous year of 2,703—an excess of 336 cases over the average annual increase for the decennium. Among curious items as to the ratio of admissions to the population I find a high ratio among those engaged in professional or intellectual pursuits. For example, the ratio for the clergy was 10.7, for lawyers 16.7, doctors 14.2, literary and scientific persons 19.4, engineers 49.8, artists, sculptors, etc., 25.4 The remarkable figure for engineers is paralleled among the less cultured classes by 51.2 for ironworkers and 40.3 for hawkers (male and female) and costermongers.

As to causes, the report assigns 22.6 of total admissions to heredity and states that prolonged mental stress is more commonly assigned in private (21.6 per cent.) than in pauper cases; that sudden mental stress is also more common among the former, particularly in females. Of toxic influences alcohol was assigned among private patients in males 17.3, females 7.1 In paupers, males 24, females 9.1, and there was a family history of alcoholism in 5.3 of both sexes.

King Edward's Hospital Fund has received the report of the committee it appointed in May to inquire into the expenses of entertainments arranged for the benefit of charities. The revised uniform system of accounts requires, when the hospital is responsible, that the income and expenditure show the results, and the committee advises that detailed estimates be formed beforehand, and, further, that the question whether the possible receipts are worth the risk entailed. When outside agencies organize the entertainment the hospital would have less risk, but the precautions ought to be proportionate. In all cases an audited statement of receipts and expenses, with full details, should be required. A rule exists at some hospitals that permission to use the name of the institution is granted only where the governing body has a voice in the management of the entertainment. It is not proposed now to formulate rules binding on hospitals, but it is hoped the perusal of the report may assist managing committees to frame their own regulations.

The managers of the Anti-Vivisection Hospital are so annoyed with the remarks made at the meeting of the Sunday Fund, which I reported last week, that they have resolved to refuse the grant made or any grant "until it can be voted in an impartial and dignified manner."

Dr. Anton Bricul, of the Liverpool Tropical School, is to be director of the newly founded Australian School of Tropical Medicine. He was assistant to Professor Chiara, of Prague, and was attracted to Liverpool by the Johnston International Fellowship. His work on the trypanosomes is well known. He and Dr. Thomas introduced citoxyl as a remedy for sleeping sickness.

The death of Dr. Alexander Fraser, the popular professor of anatomy at the Royal College of Surgeons in Ireland, on the 25th ult., will be felt as a great loss in the Irish school and regretted by numerous pupils and friends as well as colleagues. On completing the 25th year of his professorship he was presented with a check in a silver casket. He made numerous contributions to his science, chiefly in the Transactions of the Royal Society and Royal Academy of Medicine.

Progress of Medical Science.

The Boston Medical and Surgical Journal, August 19, 1909.

The Intravenous Administration of Strophanthin in Other Than Cardiac Disease, with Special Reference to Its Use in Collapse in the Course of Pneumonia.—A. K. Stone states that most observers agree with Fraenkel that 1 mg. of the strophanthin properly introduced into the venous circulation produces no unpleasant reaction and calls forth a prompt response on the part of the failing heart, which shows itself by the slowing and strengthening of the beat. The change for the better appears in from five to fifteen minutes and usually lasts from twelve to eighteen hours. The cases most favorable for its administration seem to be those of mitral disease with failing compensation; next, those cases of arteriosclerosis where there is but little renal involvement and where the heart has dilated and become incompetent. Pure renal cases with struggling heart are not only not helped but often retarded in their progress. In several cases where death has occurred in the course of the administration of strophanthin, repeated or frequent doses have been given, or it has been given to patients who have already had digitalis pushed to the limit of safety and the sudden addition of strophanthin has produced collapse. In the introduction of strophanthin great care must be taken that the solution be injected into the blood stream. For the majority of cases the median basilic vein at the bend of the elbow will be found to be the one easiest of access. Liebermeister states as his belief that the use of strophanthin would enable a certain number of severe pneumonia cases to be carried along until the patient was able to eliminate the toxin of pneumococcus and to get on the road to recovery. Dr. Stone cites several cases in his experience which confirm this statement. He does not advocate the use of strophanthin as a specific for desperate cases of pneumonia, but believes that in certain cases of collapse, due to cardiac weakness, the physician has in strophanthin a drug which will act so promptly and powerfully and will enable the patient to rally and the heart to resume its work. The large amounts of urine passed by these patients following the crisis of pneumonia makes it seem that strophanthin has to do with the production of diuresis, by means of which the toxic products are more rapidly eliminated than would otherwise be the case. When the patient has grown weaker and weaker in the course of his disease, whether it be pneumonia or typhoid fever, this drug will have little effect.

Stenosis of the Larynx.—After reporting three cases of stenosis of the larynx following intubation for diphtheria, Richard H. Johnston says that as such patients usually wear tracheal cannula the easiest treatment is dilatation from below upwards. With this procedure there

is danger of making a false passage. If there is an opening in the larynx, however small, the sound will probably find it and pass through without damage. This treatment should not be resorted to until a careful examination has been made under direct laryngoscopy. With the knowledge thus obtained one may be able to resort at once to intubation, which is the logical method of treating incomplete stenosis. In complete obstruction we may succeed in establishing an opening through the direct laryngoscope which must be kept open by intubation. After months of intubation we may remove the tube and find that the patient is not cured. Rogers believes that practically every case can eventually be cured by retained intubation tubes. He is opposed to any form of external operation and dispenses with the tracheal cannula as soon as possible. In the early stage when the difficulty of breathing appears it is of paramount importance to have the larynx examined. A certain number of patients can be cured before complete stenosis takes place; after complete closure takes place the difficulties are increased and the treatment prolonged months and even years.

New York Medical Journal, August 21, 1909.

The Pharyngoscope: A New Method of Examination of the Nasopharynx and Larynx.—This instrument, devised by Harold Hays, is composed of a horizontal and vertical shaft which join each other at right angles, at the outer third, so that the instrument may be used as a tongue depressor. The inner portion of the horizontal shaft consists of a central circular tube with an electric light carrier on either side, the three components being incorporated in a flat piece of metal. In the central tube is inserted the telescope, which is made on the principle of the Otis cystoscope. To the eye piece is attached a little metal ball, which indicates the position of the lens. The horizontal shaft, including the telescope, is about eight inches long and the widest portion is less than five-eighths of an inch. There is an arrangement for cutting off the electrical current so that the lamps need not be turned on until the instrument is in the mouth. The advantages of this pharyngoscope are: 1. That the instrument can be used without any of the usual difficulties encountered by the patient and the examiner, while a much more distinct and larger view of the parts is obtained. 2. One can see adenoid and tubal conditions. 3. In the examination of the larynx it is unnecessary for the patient to protrude his tongue; the larynx is examined with the mouth closed. 4. Applications to the nasopharynx can be made under direct vision. 5. Eustachian catheterization can be accomplished more readily as one is able to see the catheter go directly into the tube. 6. The posterior pillars of the fauces, the base of the tongue, the lingual tonsil, and the epiglottis are distinctly seen.

The Roentgen Rays in the Diagnosis of Carcinoma of the Stomach.—George E. Pfahler concludes that by means of the Roentgen rays gastric carcinoma is demonstrable when it changes the course of the food through the stomach, when it decreases the volume, interferes with peristaltic action, fixes or displaces the stomach, causes an indentation in the stomach wall, or modifies the rate of evacuation of the gastric contents. He believes that with this aid a diagnosis can be made earlier than has hitherto been possible, but that owing to the fact that a Roentgen ray study is tedious and expensive each case should first be studied well clinically. At present it is impossible to differentiate a stenosis of the pylorus due to old ulcer and that due to carcinoma, but this is not important, since the line of treatment is the same. Great caution and thoroughness will have to be observed or this valuable method of investigation will fall into discredit. No case is thoroughly studied for carcinoma unless both the screen and the plate are used. Generally the standing posture with the abdomen against the plate or screen gives the most evidence. The next most valuable position is with the patient lying on the abdomen for posterior anterior view. At the beginning of an examination it is best to use a tablespoonful of a mixture of bismuth and water, as this gives the greatest density with the greatest fluidity. For general use and for further distention of the stomach a mixture of bismuth and kefir is most serviceable.

The Action of Glandular Extracts upon Tetany After Parathyroidectomy.—Isaac Ott and John C. Scott describe experiments on 60 cats and two dogs upon which they made 133 observations. In cats, when all parathyroids were removed, symptoms of tetany came on in about forty-eight hours. In some old cats, some time after removal of the parathyroids and careful examination of the thymus, no tetany ensued for two weeks. It is probable that the well developed pituitary of older animals was sufficient to delay the attack of tetany, although the animals were kept on a meat diet, which favors tetany. About three hours after the subcutaneous injection of pituitary extract in animals that had tetany the symptoms began to disappear. The whole bearing of the animal would change, but at the end of twenty-four hours the tetany would again appear. In no case was death prevented by the repeated injection of pituitary extract. Pituitary was also injected by the vein, but the best results were obtained by subcutaneous injections. It was demonstrated that neither calcium nor its combination with other salts was concerned in the action of the pituitary. Observations showed that it is an organic body in the pituitary that abates the tetany. They tried also pituitrin and found that it acted rapidly, but that its action was much more fugitive than the pituitary extract. Adrenalin was given by the jugular, in the cat, and some improvement was noted. Iodothyrine was also given by the jugular, and it had a quieting action on the tremor. Mammary gland, thymus, testicle, prostate, spleen, spinal cord (all rubbed with distilled water), and Poehl's spermin had no effect upon the tetany. Pancreas had a quieting effect in seven cases out of ten. The experiments did not show that there was any difference in the comparative value of calcium lactate and pituitary extract. It is inferrable that the infundibular lobe is the active part of the gland in antagonizing the tetany after the removal of the parathyroids. Tetany is not due to a want of calcium, but to a poison in the blood. The removal of the parathyroids in the cat produces paresthesia, probably an action on the center of touch, as shown by the lifting of the feet as though they were wet with water.

Journal of the American Medical Association, August 21, 1909.

Primary Hemorrhagic Glaucoma.—M. Frank gives a detailed account of a case which presents certain clinical and diagnostic peculiarities that render it of interest. It points out that a broad iridectomy, freeing the filtration angle, is not always a preventive of glaucoma, though iridectomy is the best method of treating the acute disease. It further indicates that diminished depth of the anterior chamber and narrowing or closure of the filtration angle are not absolutely essential for the production of glaucomatous symptoms, but that perhaps hypersecretion and changes in the character of the fluids of the eye impeding proper filtration are sometimes concerned in the onset of glaucoma. The clinical picture in the case was that of an acute hemorrhagic glaucoma, but iridectomy was at first considered inadvisable, and paracentesis of the cornea with later posterior sclerotomy were performed, and as a later resort a month afterward a broad iridectomy was performed, and lastly an enucleation of the left eye, the right eye having become affected and sympathetic inflammation being feared. A careful microscopic examination of the left eye was made after removal, the details of which are given. There were no anatomic or histologic evidences of sympathetic inflammation discovered, this being in marked disagreement with the clinical symptoms. The presence of a chronic iridocyclitis throws some doubt on the diagnosis of primary glaucoma, and it is possible that an anterior uveitis may have preceded, without symptoms, and caused the glaucoma. Frank expresses the opinion that the acute glaucoma here can be more rationally accounted for by some vascular disturbance, probably due to a toxemia, rather than by gross obstruction of the filtration zone.

Hair Ball of Stomach.—W. W. Butterworth has found forty-three cases of hair-cast of the stomach reported in the literature. It is most common in women, thirty-nine of the forty-three being of that sex, and most of the cases are from literature of English-speaking people. His personal observation was in a girl eight years old, from whom at autopsy a hair ball weighing three and three-quarter ounces was taken. She had suffered from abdominal symptoms for about four weeks before death. Butterworth comments that the habit of eating hair is most often commenced in early life. His own patient was a victim of hook worm disease, which may have had a part in the etiology. He finds but one other case recorded where an intestinal parasite seemed to play a part in the etiology. He thinks it probable that the custom of young girls wearing their hair loose is an important factor in setting up a habit of biting it or passing it between the teeth. Various reasons are given for the abnormal tendency. One patient said she swallowed the hair because "it was so nice," another to make her voice clear, another to clean her tongue, etc. In at least three cases the diagnosis was made before death by the passage of small tufts of hair through the bowel. It is remarkable how little the general health suffers, considering the duration of the habit. Eventually the limit of

toleration is reached and Nature protests. Pain is fairly constant, vomiting is common, and alternating attacks of constipation and diarrhea are the usual rule. Eventually the breath becomes very offensive, there is marked anemia, ingestion of food is difficult, emaciation and weakness increase, and the patient finally, unless relieved by laparotomy, dies from inanition or perforation.

Adenoids in Infancy.—R. G. Freeman criticises the neglect of adenoids in early infancy, as they interfere with the proper development of the child by reflex action, by the irritation they produce, and the obstruction they cause. The post-nasal pharynx at birth is a space only one-quarter inch high by one-third inch wide, so that a very slight adenoid hypertrophy at this period will cause obstruction. At the end of the first year it is nearly doubled in size. It often produces symptoms in the first days of life, and the mistake is sometimes made of diagnosing specific disease. The snuffles are specially marked while the child is nursing, and result from an adenoid which produces irritation, and if large enough to obstruct the pharynx there is mouth breathing. Other causes may produce mouth breathing, but adenoids do so most frequently during the first year of life. A third indication of the condition is the appearance of recurrent colds, which during the first year are usually caused by adenoids. Another most characteristic sign is a persistent cough, sometimes simulating whooping cough, without any other indication in the pharynx or bronchi to account for it. A fifth and most dangerous condition is otitis media. It is not always easy in a very young infant to determine the presence of adenoids, but it can be done by rapid manipulation. The right index finger being rapidly passed into the mouth while the jaw is held open by the ends of the fingers of the left hand pressing on the teeth, the rough surface of the adenoid can be detected by the skilled physician, and sometimes so quickly that the baby does not even cry. He describes the operation of removal of the adenoids, which he says can be done quickly without an anesthetic and with very little shock or lasting fright. If an anesthetic is used it should be nitrous oxid, and only enough to produce primary anesthesia, and the parents should be warned of the possibility of a lymphatic constitution and the dangers of anesthesia in that case. In conclusion, he says that adenoid hypertrophy which causes persistent symptoms should be operated on as early as the third or fourth month of life. The operation should be done rapidly and without an anesthetic.

Radioactive Charcoal.—J. B. Shober has investigated the radioactive property of cocoanut charcoal. He passed a slow current of air through a celluloid tube, eight inches long and three-quarters of an inch in diameter, coated on the inside with a collodian solution containing one mgm. of strong radium bromid, into a porcelain vessel containing a quantity of cocoanut charcoal. At the end of a week he found the charcoal strongly radioactive, discharging his electroscope more rapidly than would a specimen of high grade pitchblende ore. He then spread a quantity of this charcoal over a key on an *x*-ray plate and obtained a very strong picture of the key after an exposure of four days. He made the same tests with untreated charcoal with negative results. Tests of the degree of radioactivity of cocoanut charcoal thus treated and its rate of decay, made for him by Mr. D. H. Kabakjain, are given in detail, and show that this substance can be raised to from 110 to 160 times the radioactivity of uranium oxid and retains this for a number of days before it is entirely dissipated. He quotes also from R. W. Boyle (*Phil. Mag.*, March, 1909) as to the radioactive emanations of charcoal, as confirmatory of his findings, and proposes to utilize this property for external and internal radium treatment. He is able to obtain on one charge sufficient charcoal of 140 activity to fill five small test tubes each containing enough to supply a patient for fourteen days, the dose being about as much as would cover a dime, taken three times a day. He feels therefore that he has developed a very easy and simple method of utilizing radioactive emanation internally as well as externally, for there is no reason why the charcoal should not be incorporated in ointments or solutions and applied in cases of leg ulcer, lupus, etc. The internal administration would require study. It has been utilized somewhat in Germany and reported on by Nagelschmidt, Lowenthal, and by Laqueur. No effects have been observed except the ordinary reaction, by which is probably meant the erythema. Nagelschmidt thinks that the emanation treatment may be contraindicated in certain cases, as it has appeared to cause hemorrhage from latent gastric ulcer. The class of cases in which he is inclined to test it are certain chronic diseases treated with difficulty by other methods, such as inflammation and ulceration in the gastrointestinal tract, malignant disease, chronic muscular rheumatism, tuberculosis, etc. He submits the following observations for the consideration of the medical profession: "1. Cocoanut charcoal is an inert substance and can be administered freely internally. 2. Cocoanut charcoal will absorb and retain the emanation of radium and, when treated by my method, can be raised to a very high degree of radioactivity compared to water, namely, from 200 to 300 times the radioactivity of the most radioactive water. 3. It can be prepared with but small expense. The same radium can be used over and over again indefinitely; none of the radium need be lost. 4. The charcoal will retain its radioactivity for at least two weeks and the method of administration is simple. 5. The beneficial results of radioactive spring waters in many diseases, and the results obtained abroad by the administration of weak emanation preparations, warrants the belief that in this highly radioactive charcoal we have an agent, the use of which will be followed by the same, if not better, results. 6. The local application of emanation cocoanut charcoal in tubes or capsules or incorporated in ointments or solutions is worthy of trial."

The Lancet, August 14, 1909.

Congenital, Hereditary, and Family Hematuria.—John Aitken reports seven cases of this rare condition in one family which has been under his observation for seven years. The family is composed of 17 persons, of whom 10 have suffered from hematuria. Testimony is conflicting as to whether the great-grandmother had hematuria or not; she died at an advanced age of "senility" with dropsy. Her only child, a daughter, had hematuria, married, and had eight children, of whom three are alive. There is no evidence of any of those who died having had hematuria. Of the three living there is no evidence of the eldest son, 31 years of age, having ever had hematuria, but his six children have all been hematuric: the second son, aged 28, has suffered from hematuria, and also his only child, aged two years. The daughter, aged 23 years, and unmarried, has hematuria. It is interesting to know that the hematuria has been inherited first through the female side, and then transmitted on two occasions through the male side, in one case the transmitting male not being affected. In the family reported by Guthrie, in which 12 members of a family of 15, covering two generations, were affected the hematuria was transmitted only through the female side. In the six children having hematuria the condition is marked by acute exacerbations. There has never been at any time in any of the cases edema, nor pain on micturition, nor renal tenderness. None of them have suffered from scarlet fever, rheumatism, or gravel, nor have any shown symptoms of scurvy, purpura, or Raynaud's disease. There is no history of other hemorrhage in any of the cases. Guthrie says that the condition does not seem to endanger life or even health as a general rule. But one of the cases which Dr. Aitken reports died from acute nephritis with uremia, and this would necessitate a very guarded prognosis for the other members of the family. It is uncertain whether these cases of hereditary hematuria are of vasomotor origin or are due to structural changes in the renal vessels or tissues.

A Case of Acute Pancreatitis with Fat Necrosis.—F. W. Goyder relates the history of a woman, aged 36 years, admitted to the hospital, complaining of attacks of abdominal pain and vomiting. Examination was difficult, owing to fat, but the abdomen was distended, slightly tender in the right loin and more resistant on the right side than on the left. There was no iliac tenderness. The patient's chief complaint was difficulty in breathing, especially at night. After several weeks a diagnosis was made of abscess in the right loin, secondary perhaps to appendicitis. Incision into the loin was followed by the discovery of an extensive cavity filled with a brownish, fetid fluid containing debris with a few acicular crystals and cohesive brownish masses resembling blood clots. The wound discharged the same kind of matter. Respiratory difficulties, increasing cardiac insufficiency and general weakness, resulted in death in six weeks after the onset of the illness. Autopsy showed that the thoracic cavity was much encroached upon by the distended abdomen; the lungs were congested at the bases, but not consolidated. The liver was large, soft, and fatty; the gall-bladder was thickened and contained many gallstones. Retroperitoneally, communicating with the sloughing operation wound, was an irregular cavity with necrotic walls. It was roughly H shaped, the right hand limb extending from the iliac crest, behind the liver to the diaphragm, the connecting limb surrounding the pancreas, and the left limb lying behind the spleen and the descending colon. The contents of the cavity were like those found at the operation. He read in this case the following order of events: (1) gallstone with one or more attacks of cholecystitis:

(2) a secondary pancreatitis, (3) a pancreatic lesion causing escape of the secretion behind the peritoneum; and (4) retroperitoneal necrosis of the very abundant fat which is present in this region with formation of the tumor in the right loin.

British Medical Journal, August 14, 1909.

Acute Necrosis of Skin.—Carey Coombs reports the case of a woman whose illness began with intermittent fever, pain along the course of the sciatic nerves, followed after a few days by the appearance of bullæ, like those of ecthyma near the tuber ischii. These bullæ formed sores which healed in the course of three months. Later a bulla appeared on the inner side of the right knee, and in the course of two months the whole skin was gone from the right leg. On some days more than a square inch of skin died. The process usually began by the appearance of serum under the epidermis at the growing point of the necrotic area; the cutis vera died in a few hours; when it was cut off granulations were found growing beneath. Eighteen months after the disease started the whole surface had skinned over. Some six months later the skin began to die again, and the patient's temperature was above 99 for twenty-five weeks, the highest being 104. The treatment consisted in quinine and iron throughout the illness. Opium was given at night and was added to the ointment composed of lanoline containing tincture of benzoin. Boric acid in carbolic solution was used at first and idoform was added later, and the edges of the wound were painted with peroxide of hydrogen. At the beginning of the second attack the sores were ionized, but it seemed that the hydrogen peroxide and iodoform lotion had a better effect. The case is remarkable because of the persistance of the high temperature, the appearance and progress of the sore, and the fact that the first nurse had to leave because her hands became infected, suggesting a bacterial cause. Syphilis and tuberculosis might be dismissed, as the patient and her children had never shown any tendency suggestive of either.

Prognosis in Tetanus.—John Patton cites two cases in which antitetanus serum was used freely and yet the course of the disease and the results were quite different. The first case, a miner, aged 52, with a large fungating mass on the outer aspect of the left thigh of two years duration. A large tender swelling was also found in the hypogastric and left iliac region. He presented the symptoms of tetanus, but under the injection of antitetanus serum and the daily application of hydrogen peroxide the patient improved and it was possible to amputate the leg, after which he recovered. The tetanus bacilli were found in large numbers in the epitheliomatous mass. The second case was a man, aged 38, who presented the symptoms of tetanus a week after having sustained an injury to his thumb, dislocating it at the interphalangeal joint and breaking the skin so that the head of the second phalanx protruded through the aperture. The finger had been steeped in carbolic solution 1 to 40 for a half hour before reduction and had been dressed daily afterward. Suppuration started, however. In spite of large doses of antitetanus serum the patient had a spasm on the morning following his admission to the hospital. Chloroform was given, and although pulse and respiration ceased, they were ultimately re-established. The following morning the patient had another spasm and died. At autopsy pus was found in the tendon sheath extending to the elbow and containing the tetanus bacillus. It seems evident that the difference in the results in these cases was due to the difference in the site of the infection and the facility for multiplication offered to the bacillus. The conclusion to be drawn is that the synovial fluid of the tendon sheath is an excellent medium for the growth of the tetanus bacillus and that steeping in carbolic will not prevent the occurrence of tetanus if the tendon sheaths are exposed. When tetanus has occurred the sheath of the tendon should be freely opened up, even although there is no apparent necessity to do this. Hydrogen peroxide is capable of destroying the tetanus bacillus if the microorganism and the remedy can be brought into intimate contact. It is impossible to say whether the antitetanus serum was of any value or not in these cases.

The Sterilization of the Skin of Operation Areas.—Painting the skin of operation areas with iodine (10 per cent) has been recommended by several authorities recently but Dr. Lionel Stretton feared to risk using a solution as strong as this, and thought that a weaker solution might be effective, and he accordingly used the tincture of iodine B. P., which is about a quarter of the strength. He used it in 51 consecutive cases with no failures, and in six septic cases with satisfactory results. The ages of the patients varied from two months to 84 years, and in none did the iodine application cause the slightest discomfort. The cases were representative, including knee joint, hernia, fracture, etc. The first and only dressing was made on the eighth day, when the stitches were removed and the line of incision with a margin of one inch painted again with the iodine solution. No other preparation of any kind was used. The solution used was made of one part of stronger solution of iodine B. P. and three parts of spirit. The spirit was made by mixing equal parts of spt. vini meth. and distilled water. The following reasons are given for the use of the iodine solution: 1. It is an efficient method of skin sterilization. 2. The surgeon can be absolutely certain that it has been applied. 3. It is quickly and easily applied. 4. It saves the patient the suffering of a preparation which is at present very lengthy and very disagreeable. 5. It obviates the necessity of shaving. 6. It saves an enormous amount of labor on the part of assistants and nurses, and consequently a lessened expenditure. 7. It saves the cost of preparatory materials and dressings. Furthermore iodine can be used in emergency cases in which preparation by any of the usual methods is wholly out of the question.

Berliner klinische Wochenschrift, August 2, 1909.

Abdominal Symptoms in Beginning Pneumonia.—Glaserfeld calls attention to the difficulty occasionally met in differentiating between appendicitis and early pneumonia with abdominal symptoms. Especially in children the early symptoms of pneumonia may be confined entirely to the abdomen and it is at times almost impossible to make a correct diagnosis. The patients are taken ill suddenly with pain in the right abdomen, slight rigidity of the abdominal walls, high fever, and either diarrhea or constipation. In many cases laparotomy has been performed and a normal appendix found, the typical symptoms of pneumonia appearing first after two to four days. He reports two cases, one of supposed lead colic in a man who had been subject to chronic lead poisoning. The abdomen was boardlike and the pain intense. The lungs were clear. The second day the temperature rose, meteorism appeared, and the abdomen was very tender; constipation was marked. On the fourth day the abdominal signs disappeared and a pneumonia of the left base was found. The other case was more typical of appendicitis, but proved to be pneumonia of the right base. Both cases recovered after developing pulmonary abscesses. Glaserfeld considers the important points in diagnosis to be: (1) The facies. Though these patients with "abdominal pneumonia" may be as pale as in true appendicitis they do not show the anxiety which one sees in the face of the latter when one handles the tender portions of the abdomen; they lack the facies abdominalis. (2) The tongue is usually moist and but slightly coated (3) Rapidity of respiration, attention to which is much too frequently neglected. (4) Abdominal spasm. In pneumonia this is more apt to be general than local. The tenderness is more superficial and deep pressure over the appendix does not cause such severe pain. (5) Careful physical examination of the lungs.

Münchener medizinische Wochenschrift, August 3, 1909.

The Etiology of Arthritis Deformans.—Heckmann says that arthritis deformans may be monarticular or polyarticular. In four cases of the monarticular form definite histories of syphilis were given, and they reacted positive to the Wassermann, Wassermann-Noguchi, and globulin (Noguchi) tests. In eleven cases of polyarticular arthritis also either suggestive or positive syphilitic histories were given in most of the cases, and in all the serum tests were positive. The author says that he believes that the monarticular form of arthritis deformans is the immediate result of trauma but that the underlying cause is syphilis. The lues is responsible for the fact that the contusion of the joint and the synovitis do not heal as they do in a healthy person, but go on to a progressive arthritis deformans. Two factors are necessary for the polyarticular form—a rheumatic disposition and constitutional syphilis. Polyarthritis deformans is, at least in a large percentage of cases, either a chronic or a subacute articular rheumatism in syphilities. The syphilis is here also responsible for the rheumatic affection not healing but going on to form the polyarthritis deformans. The treatment of these cases by antisyphilitic methods has not been carried out long enough to be reported. Patients who are anemic and emaciated, as is well known, do not tolerate any large doses of potassium iodide, and in such cases the author advises that mercurial inunctions should be used first and the iodides given only after the general condition has improved.

Book Reviews.

Treatment of the Diseases of Children. By Charles Gilmore Kerley, Professor of Diseases of Children in the New York Polyclinic Medical School and Hospital, Attending Physician to the New York Infant Asylum and Maternity, Assistant Attending Physician to the Babies' Hospital, Consulting Physician to the Sevilla Home for Girls, and to the New York Home for Destitute and Crippled Children; Consulting Pediatrist to the Greenwich (Connecticut) Hospital. Second edition, revised. Philadelphia and London: W. B. Saunders Company, 1909.

It is pleasing to note this new edition, and to observe that it is very little larger than its predecessor. The only appreciable changes are the rearrangement of some of the matter in the section on Nutrition and Growth, and the addition of two new sections. These are (1) on the care of acute illness, and (2) on vaccine therapy, and new diagnostic methods. It may be well to remind our readers that this book is written specially for the general practitioner, and is not intended either for the specialist in children's diseases or for the undergraduate student. Further, it contains all that a physician is likely to look for, and is so clearly and forcibly written that it is impossible for any one not to understand the author's meaning.

Dietetics for Nurses. By Julius Friedenwald, M.D., Professor of Gastroenterology in the College of Physicians and Surgeons, Baltimore, and John Ruhräh, M.D., Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1909.

In this new edition the part dealing with milk has been rewritten and enlarged; sections have been added on the detection of certain food adulterations and preservatives, and other slight changes have also been made. The work remains one of the most serviceable books on the subject of dietetics, and, while written primarily for nurses, it will be found worthy of the attention and study of both physicians and students.

A Text-Book of Medical Chemistry and Toxicology. By James W. Holland, A.M., M.D., Professor of Medical Chemistry and Toxicology and Dean of Jefferson Medical College, Philadelphia. Fully illustrated. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1908.

The author of this work has taken advantage of a new edition to correct some errors which were found in the former edition, and also to incorporate some new material. The chief additions are paragraphs referring to the electronic theory; chemical equilibrium; Kjeldahl's method for determining nitrogen; classifications of alkaloids and of proteins; chemistry of foods and their changes in the body; synthesis of proteins, and some improvements in the urinary tests. This revision adds to the value of the work, and the book is one which is calculated to be of much service both to students and to physicians. In addition to its other good points, it should be stated that it is more readable than most other text-books on chemistry.

Seven Hundred Surgical Suggestions. Practical Brevities in Diagnosis and Treatment. By Walter M. Brickner, Assistant Adjunct Surgeon Mount Sinai Hospital; Eli Moschcowitz, Assistant Physician Mount Sinai Hospital Dispensary, and Harold M. Hays, Associate Editor *American Journal of Surgery*. New York: Surgery Publishing Company, 1909.

This little volume might well be called the almanac of surgery, for while, unlike the nautical almanac, which gravely forecasts the future, or the farmers' almanac, which foretells portentous agricultural events, it is as full of facts as the best of them. Most unfortunately, there is no adequate way of turning rapidly to the information, but the very nature of the book may make this impossible. It represents an immense amount of work, which is carefully and accurately presented.

Etudes Anatomo-Cliniques. Coeur Vaisseaux, Poumons. Par le Dr. Raymond Tripier, Professeur à la Faculté de Médecine de Lyon. Avec 32 figures dans le texte. Paris: G. Steinheil, Editeur, 1909.

This volume contains a series of clinical studies on certain phases of the diseases of the vessels, heart, and lungs. In his discussion on the pathogenesis of endocarditis the writer lays stress upon the tuberculous origin of certain types of valvular lesions. The part which is played by chronic arteriosclerosis in the production of renal and cardiac lesions is very fully treated. The remainder of the volume is devoted to a consideration of the pathology of pulmonary emphysema and the relations which exist between this disease and other lesions of the lung. A separate chapter concerns the reciprocal relationship between the diseases of the heart and lungs. The style is clear, and, while the volume does not present much that is novel in fact, its eminent readability will commend it to those who wish to freshen their memories and obtain new lore on this important phase of medicine.

Inborn Errors of Metabolism. The Croonian Lectures Delivered before the Royal College of Physicians of London, in June, 1908. By Archibald E. Garrod, D.M., M.A., Oxon, Fellow of the Royal College of Physicians, Assistant Physician to and Lecturer on Chemical Pathology at St. Bartholomew's Hospital, Physician to the Hospital for Sick Children, Great Ormond Street. London: Henry Frowde; Hodder & Stoughton, 1909.

The revised collection of Garrod's Croonian Lectures of 1908 is an excellent example of the admirable work in the chemistry of metabolism which is now being done by the younger group of scientific workers in England. This volume forms a part of a series of such books, each written by a master in the subject. Garrod's name has long been associated with the matter of which he treats, especially alkaptonuria and cystinuria. It seems curious that albinism should be included as a disease of metabolism, and the author recognizes the weakness of his position, though he makes a strong plea for careful chemical studies along the line of pigment defects and Mendelian heredity. The other three conditions, which include pentosuria in addition to those already mentioned, are very fully presented, and every one who is in the least interestsed in the progress of the chemical side of medicine should peruse this little volume.

Sammlung klinischer Abhandlungen über Pathologie und Therapie der Stoffwechsel und Ernährungsstörungen. Herausgegeben von Prof. Dr. Carl von Noorden. 7 und 8 Heft. Über die Behandlung einiger wichtigen Stoffwechselstörungen (Hungerzustand, Mastkuren, Entfettungskuren, Gicht). Berlin: Verlag von August Hirschwald, 1909.

This small monograph forms the seventh and eighth parts of the series published by von Noorden during the past nine years. The subject is the treatment of some of the more important conditions in which the bodily metabolism is disturbed, and inasmuch as such treatment usually consists in a general reduction in the quantity of food, or in the elimination of certain articles of diet, a chapter on the changes in metabolism which occur when a patient is put upon a low diet is very properly introduced. One section is devoted to the treatment of obesity and another to the dietetic treatment of gout. As in all the numbers of this series the form of presentation is as simple as possible, all unnecessary scientific matter being eliminated, and the practical aspect of the various problems emphasized as much as may be. It is to be hoped that a translation of this book will be undertaken in order to make it accessible to those physicians who do not read German.

Moritz Schmidt: Die Krankheiten der oberen Luftwege, aus der Praxis fuer die Praxis. Vierte umgearbeitete Auflage von Prof. Dr. Edmund Meyer in Berlin; mit 180 Textfiguren. 1 Heliogravur und 5 Tafeln in Farbendruck. Berlin: Verlag von Julius Springer, 1909.

Professor Schmidt was fortunate in being able to secure during the last days of his life Professor Meyer's consent to edit a new edition of his well-known textbook, and right well has the latter's task been performed. The frontispiece is a handsome portrait of the deceased professor, and to those who ever had the privilege of meeting him the sight of this representation of his refined and benignant face awakens emotions not easily expressed. Throughout the successive editions which the master himself carried through the press the idea that the work was that of a practitioner for the benefit of his fellows was always prominent, and this same idea has been followed out in the present edition. This contains more pages, and each page is larger than in the previous editions, so that the book as a whole is considerably increased in size and matter. An elaborate table of contents makes reference very easy, and it is supplemented by a copious index. Full particulars are given with reference to the newer procedures, as the submucous reaction of the septum, bronchoscopy, esophagoscopy, etc. One great charm of the work has always been the grouping of topics; thus, neoplasms of the upper air tract, instead of a division and consideration in separate chapters of tumors of the nose, pharnyx, larynx, etc. It might well be wished that a translation of the work into English could be made, for we regard it as one of the best textbooks now extant in this field of medicine.

Der Einfluss der Mineralwässer auf Verdauungs- und Stoffwechsel-Krankheiten. Von Dr. Robert Baumstark in Homburg v. d. H. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1909.

In recent years a very considerable amount of attention has been directed, especially in Germany, to the action of mineral waters on various types of chronic diseases, without perhaps any very astonishing practical results. In this pamphlet are assembled the conclusions of many of these studies, and the physician will find it a useful compendium of the most recent knowledge on the subject.

Practical Points in Anesthesia. By Frederick Emil Neef. New York: Surgery Publishing Company, 1908.

This concise little volume of fifty pages covers the subject matter as adequately as many larger books, and can be recommended to all.

La Nuova Scienza Medica. Ossia la sifilide ereditaria ed acquisita in rapporto alle malattie del corpo umano. Studi ed osservazioni ad uso dei medici pratici. Per il Dr. Pasquale Fusco. Volume I. Roma: Tipografia "La Speranza," 1909.

Those who are interested in the rather novel theory that tuberculosis is only the last stage of an acquired or hereditary syphilis will find this subject discussed in all its phases in this small volume.

Studies on Immunization and Their Application to the Diagnosis and Treatment of Bacterial Infections. By Sir A. E. Wright, M.D., F.R.S., Director of the Department for Therapeutic Immunization, St. Mary's Hospital, London, W.; Late Professor of Pathology, Army Medical School, Netley. London: Archibald Constable & Co., Ltd., 1909.

Despite the fact that the interest of the medical public in the determination of the opsonic index and the treatment of disease based upon such determinations has somewhat waned during the past two years, the scientific value of Denys' and Wright's discovery is still as great as ever, and this collective series of studies by A. E. Wright and his pupils forms an extremely useful addition to the literature of the subject, especially as many of the most important and fundamental papers are in the rather inaccessible Proceedings of the Royal Society of London. The first group of articles, dating between 1897 and 1899, is concerned with the theoretical and practical value of the agglutination test, especially in typhoid and Malta fevers. Two other papers treat of bactericidal substances, while the remainder of the contents is devoted to studies on the opsonins and on therapeutic immunization. The volume is an admirable example of English bookmaking, being printed on a light, unglazed paper, which makes it very easy to read.

Further Advances in Physiology. Edited by Leonard Hill, M.B., F.R.S. Contributors: Benjamin Moore, M.A., D.Sc.; Martin Flack, M.A., B.M.; Thomas Lewis, M.D., D.Sc.; Leonard Hill, M.B., F.R.S.; Arthur Keith, M.D.; M. S. Pembrey, M.A., M.D.; N. H. Alcock, M.D.; Joseph Shaw Bolton, M.D., M.R.C.P.; M. Greenwood, Jr., M.R.C.S. With Diagrams. New York: Longmans, Green & Co.; London: Edward Arnold, 1909.

The present volume is a sequel to and amplification of "Recent Advances in Physiology," issued under the same able editorship something over two years ago. Like that work, it consists of a series of articles on subjects in the domain of physiology that have important bearings in pathology and clinical medicine, and in which noteworthy advances have recently been made. While the former volume dealt largely with problems of metabolism, secretion, and excretion, in the present one some of the late researches concerning the circulation and respiration, the neuromuscular system, and vision are discussed. The first article, by Professor B. Moore, is on the equilibrium of colloid and crystalloid in living cells, and forms what is really a very comprehensive résumé of the application of the newer teachings of physical chemistry to cellular physiology. Mr Martin Flack writes on the recent theories concerning the heart beat, and Dr. Thomas Lewis discusses the cardiogram and venous pulse. Mr. Hill's section deals with the advances in experimentation made possible by the development of Carrel's technique of vascular surgery, and also with blood pressure, its measurement in man, and its relation to edema, urinary secretion, etc. Dr. Arthur Keith's chapter is on respiration and its mechanism, and Dr. Pembrey contributes an exceedingly interesting discussion of the physiology of muscular work, in which the results obtained by the recent observations on marching soldiers are considered. Various topics belonging to the physiology of nerve, such as growth, regeneration, and the nature of the nerve impulse, are dealt with by Dr. N. Alcock, and the article on cortical localization by Dr. J. S. Bolton includes an account of much original work by himself and others. Major Greenwood's article on visual adaptation and color vision closes the volume, which, as is evident from the above enumeration, comprises a series of most interesting essays on subjects of much significance. No more instructive or agreeable volume could be suggested for the medical man's summer reading.

A Textbook of the Diseases of the Ear. By Professor Dr. Adam Politzer, Imperial-Royal Professor of Aural Therapeutics in the University of Vienna, etc., etc. Translated at the personal request of the author by Milton J. Ballin, Ph.B., M.D., Assistant Surgeon New York Ophthalmic and Aural Institute, and Clarence L. Heller, M.D. Fifth Edition, Revised and Enlarged, with 337 original illustrations. Philadelphia and New York: Lea & Febiger, 1909.

The present edition of Politzer's book has been brought thoroughly up to date, and remains in its essentials the same exhaustive treatise which was given to the world for the first time some years since. In so far as one can determine, nothing of value has been missed in the effort to make this edition suitable to the needs of the practitioner and student of medicine. Of especial value is the chapter on diseases of the labyrinth, a subject which is being pursued with such zeal by Americans. Politzer thinks the prognosis of labyrinthitis is not unfavorable, several of his patients having recovered and regained their hearing. Cases of tuberculous and cholesteatomatous origin are unfavorable. A simple catarrhal labyrinthitis often gets well, therefore operation is inadvisable save when suppuration is sure and is associated with meningitis and positive lumbar puncture.

Politzer says that the hearing after radical mastoid operation is usually worse; exceptional cases only are improved. The degree of hearing depends on the amount and density of scar tissue about the stapes. The modified radical operation seldom fulfills its purpose because all diseased tissue is not removed. Suppuration continues, or if it ceases soon returns. Cholesteatomata and granulations, with large perforation of the drum, contraindicate its use.

Diet in Health and Disease. By Julius Friedenwald, M.D., Professor of Gastroenterology in the College of Physicians and Surgeons, Baltimore, and John Ruhrāh, M.D., Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Third Edition, thoroughly revised and enlarged. Philadelphia and London: W. B. Saunders Company, 1909.

It is not surprising that a third edition of this useful work has been issued. The previous editions, while of great value, were scarcely so helpful for ready reference as the present is likely to prove. The articles on milk and on alcohol have been carefully revised, and additional information is given as to salt-free diet, rectal feeding, calorie needs of infants, etc. The section dealing with the dietetic management of tuberculosis is especially satisfying, and shows how the profession in its desire to maintain nutrition of the patient to its highest point overstepped the border line in many instances by too great insistence on forced feeding. Several useful tables have been added, notably that of Winton of the Connecticut Agricultural Station showing the composition at a glance of most of the proprietary diabetic foods. The chapter on "The Dietetic Management of Surgical Cases" deserves especial mention, since one finds this subject so diffused in the literature as to be of little immediate use to the busy surgeon. Nausea and vomiting, thirst, care of the bowels, diet in shock and after anesthesia are all described briefly but sufficiently. The tables showing the chemical composition of American food materials are instructive, and give in calories the fuel value per pound of most foods in common use in this country. Dietetics is a subject quite as important as diagnostics, and such a volume as the authors have given us should form the basis of a full working knowledge possessed by every physician, whatever be his specialty.

Rational Immunization in the Treatment of Pulmonary Tuberculosis and Other Diseases. By E. C. Hort, B.A., B.Sc., M.R.C.P. Pp. 1-75, cloth. New York: William Wood & Company, 1909.

The author uses the word heteroinoculation to denote inoculation by immune sera "from without." In the light of autolysis and anomalies of cell metabolism, production and maintenance of immunity are not questions of protection against bacteria and their products alone. Autoinoculation is a natural process of cure; hence artificial autoinoculation is immeasurably superior to all other types. Hort believes that the tuberculoopsonic index is unreliable and produces a diagram which seems to substantiate his claim. He shows a new method of interpreting temperature charts in terms of immunity curves. This is an original, brief, and valuable contribution to the study of serum therapy.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE AMERICAN POCKET MEDICAL DICTIONARY. Sixth Edition. By W. A. NEWMAN DORLAND, A.M., M.D.; 16mo; cloth; 598 pages; $1.25 net. W. B. Saunders Co., Philadelphia, Pa.

REPORT OF THE STATE COMMISSION IN LUNACY, New York State. 8vo; cloth; 1,317 pages.

REPORT OF THE METROPOLITAN WATER AND SEWERAGE BOARD. 8vo; cloth; 238 pages; illustrated.

EYE, EAR, NOSE, AND THROAT. Edited by GUSTAVUS P. HEAD, M.D. Cloth; 12mo; 366 pages; illustrated. The Year Book Publishers, Chicago, Ill.

EXPERIMENTAL PHARMACOLOGY. By CHARLES WILSON GREENE, Ph.D. 8vo; cloth; 76 pages; illustrated; $1.00 net. P. Blakiston's Son & Co., Philadelphia, Pa.

STUDIES ON IMMUNISATION. By Sir A. E. WRIGHT, M.D., F.R.S. 8vo; cloth; 490 pages; illustrated; 16 shillings. Archibald Constable & Co., Ltd., London, England.

THE ELEMENTS OF HYGIENE. By ISABEL MCISAACS. 12mo; cloth; 172 pages; illustrated; 60c. net. Macmillan Co., New York.

FURTHER ADVANCES IN PHYSIOLOGY. Edited by LEONARD HILL, M.B., F.R.S. 8vo; cloth; 440 pages; illustrated. Longmans, Green & Co., New York.

HYDROTHERAPY. By WILLIAM H. DIFFENBACH, M.D. 8vo; cloth; 267 pages; illustrated; $3.00 net. Rebman Co., New York.

SEMMELWEIS, HIS LIFE AND HIS DOCTRINE. By Sir WILLIAM J. SINCLAIR, M.A., M.D. 8vo, 369 pages; cloth; illustrated. Sherratt & Hughes, London, England.

MEDICAL JURISPRUDENCE, FORENSIC MEDICINE, AND TOXICOLOGY. By R. A. WITTHAUS, A.M., M.D., and TRACY C. BECKER, A.B., LL.B., Vol. III. 8vo, 981 pages; cloth; illustrated; $6. Wm. Wood & Co., New York.

DEUXIÈME CONGRÈS DE LA SOCIÉTÉ INTERNATIONALE DE CHIRURGIE, Vols. I et II. Par les Docteurs A. DEPAGE et L. MAYER. 8vo, 580 pages; cloth. Hayez, Imprimeur des Academies Royales de Belgique, Bruxelles, Belgium.

MYELOISCHE METAPLASIE UND FÖTALE BLUTBILDUNG UND DEREN HISTOGENESE. Von Dr. med. HEINRICH FISCHER. 8vo, 140 pages; paper; 4 marks. Julius Springer, Berlin, Germany.

STATISTICA SANITARIA DELL'ARMATA per GLI ANNI, 1901 e 1902. Folio, 284 pages; paper; illustrated. Tipografia Ditta Ludovico Cecchini, Roma, Italy.

GYNECOLOGY, PRACTICAL MEDICINE SERIES, 1909, Vol. IV. Edited by EMILIUS C. DUDLEY, A.M., M.D. 12mo, 225 pages; cloth; illustrated; $1.25. The Year Book Publishers, Chicago, Ill.

MODERN MEDICINE. Edited by WILLIAM OSLER, M.D., Vol. VI. 8vo, 799 pages; cloth; illustrated; $6 net. Lea & Febiger, Philadelphia, Pa.

MANUAL OF THE DISEASES OF THE EYE. By CHARLES H. MAY, M.D. 12mo, 391 pages; cloth; illustrated; $2 net. Wm. Wood & Co., New York.

THE MALARIAL FEVERS. By CHARLES F. CRAIG, M.D. 8vo, 477 pages; cloth; illustrated; $4.50. Wm. Wood & Co., New York.

LECTURES ON HYSTERIA. By THOMAS D. SAVILL, M.D., Lond. 8vo, 262 pages; cloth; $2.50. Wm. Wood & Co., New York.

LECTURES ON NEURASTHENIA. By THOMAS D. SAVILL, M.D., Lond. 8vo, 226 pages; cloth; $2 net. Wm. Wood & Co., New York.

ANAESTHETICS AND SURGICAL TECHNIQUE. Edited by JAMES CANTLIE, M.A., M.B., C.M., Alberd.; F.R.C.S., Eng. 12mo, 382 pages; cloth; illustrated; $3 net. Wm. Wood & Co, New York.

DIATHESIS AND OCULAR DISEASES. By A. MAITLAND RAMSEY, M.D. 12mo, 184 pages; cloth; illustrated; $2 net. Wm. Wood & Co., New York.

STATE OF PA., U. S. A., REPORT OF THE COMMISSIONER OF HEALTH. 8vo, 973 pages; cloth; illustrated. Commissioner of Health of Pennsylvania.

DIE ERSTE ÄRZTLICHE HÜLFE BEI UNFALLVERLETZTEN. Von A. KÖHLER. 8vo, 44 pages; paper; 1 mark. A. Hirschwald, Berlin, Germany.

LES MALADIES DES ENFANTS. Par V. HUTINEL. 8vo; paper; 5 vols., 808, 823, 778, 790 and 1,036 pages; 100 francs. Asselin et Houzeau, Paris, France.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of August 28, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	491	149
Diphtheria	156	14
Measles	167	9
Scarlet Fever	58	5
Smallpox	—	—
Varicella	4	—
Typhoid Fever	158	14
Whooping Cough	44	13
Cerebrospinal Meningitis	5	9
Malarial Fever		
Totals	1,083	213

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending August 27, 1909:

SMALLPOX—UNITED STATES.

THE RÔLE OF VISUAL FUNCTION IN ANIMAL AND HUMAN EVOLUTION.

By GEORGE M. GOULD, M.D.,

ITHACA, N. Y.

WHEN scientific interest first appeared it concerned those things farthest removed from the observer and of the least vital importance to him. During thousands of years the intellect gradually approached the consideration of the human being himself. Astronomy was the first of the sciences; then man discovered his own world. The beginning of biology came nearer home than geology, and through numerous approaches and standstills man finally reached his own body. The bones of that body were his first care, then physiology was found; psychology is now emerging. It is natural that the law which expresses the order of the diverse kinds of discoveries should hold when applied to the stages of progress in each individual type. It follows that in zoölogy and physiology the nearest and most important conditions which have brought about the exclusion of the unfit have been deferred for final finding and scrutiny, and we are now entering upon this last stage of accounting.

Hitherto the interaction of organism and environment has largely summarized the philosophy of biological development, followed at once by the admission that the environment is the predominant factor, and that the individual organism has but little influence upon the outside circumstance. The truth seems rather to be that, when rightly estimated, the human organism, as a whole, has largely made its own environment, and that civilization is progressively taking almost entire charge of it.

With this recreation of the environment by humanity will come the recognition of the hitherto unseen truth that the most intimate and influential part of the environment is man's own body. Following this it will also be admitted that the individual variants of organs, such as imperfect senses, traumatisms, diseases, etc., not to be accounted for by heredity, are powerful factors in making misfits and unfits of such organisms and thus excluding them from the phylum.

Whether the controversy concerning the inheritance of acquired characteristics shall be settled in one or another way, the speediest and surest method will be by the study of the action of the inheritance of disease. And especially as to those diseases which depend upon ametropia. Here is an astonishing mass of evidence collated and placed in the hand. If it were used, the controversy would soon be illuminated. The people, rightly or wrongly, also believe that they "inherited" their headaches, sick-headaches, and morbid nervous diseases. A very little careful testing would prove or disprove both the scientific and the popular faiths. Thus again, as always, what is good science is good benevolence. Pathology would soon settle more scientific and social problems than normal physiology or morphology.

This gives warrant for criticism of that too common prejudice which excludes pathology from scientific consideration. It would rather seem that all other factors combined hardly equal in efficacy that of disease in excluding the unfit from genetic function. The morbidity and mortality rates, even among animals, and certainly in human life, markedly govern the evolution and characteristics of the phylogeny.

If so much is admitted, then the function of vision has been a strangely overlooked factor in the development of fit and unfit, and in shaping animalian and human trends and products. This is because vision is the most directional component, the *sine qua non*, indeed, of that part of the environment called the body; it intermediates between that body and the more external world; between man's hands and himself; between his mentality and his corporeality. The reason for the preponderant rôle of the eye in the development of unfitness lies in the difficulties encountered in its creation and present perfecting. It has been the severest task of the biological process, and its imperfections are still a vast and growing source of the imperfections, characteristics, and failures of that process itself.

These difficulties may be roughly classified as those which relate to:

1. The embryology and optics of the eyeball.
2. The rôle of vision in the development of self-motility of the body.
3. The progress from divergence to parallelism of the optic axes, or from laterality to forward-looking.
4. The adaptations consequent upon the assumption of the vertical posture of the body.
5. The development of the shading mechanisms of the retina.
6. The struggle against astigmatism and other forms of ametropia, accommodational failure, cataract, ocular, and systemic disease.

1. In view of the fact that the ether is the chief medium connecting organism and environment, the knowledge and utilization of the external world was possible only through the development of visual function. The fundamental difficulty in the construction of the eye was to devise a mechanism which should react instantaneously, accurately, and for a lifetime to a stimulus hundreds of millions of millions slighter in kinetic energy than that, for instance, of sound waves. There is a keen suggestion of this difficulty shown by embryology. Within a few weeks after fertilization, the ovum, nearly synchronous with the differentiation of muscular tissue, shows the eyes in beginning formation. That it is so early, and that eye and muscle develop at the same time, is strikingly significant, for neither

alone, certainly not the muscular system alone, would be either possible, or of use. *Ubi motus ibi visus!* If "the ontogony repeats the phylogeny," then the long stage of coincident embryonic evolution of the visual and muscular organs demonstrates an amazingly long period during which the difficulties and imperfections of either, or of both, were overcome. Those individuals and types in which these imperfections were the greatest must have been those excluded from the phylum because of unfitness. The undoubtedly greater difficulty of device in making the eyes renders it clear what delayed the perfecting of bodily mechanism, and why the unfit were preeminently those that were visually unfit.

A still more significant fact is that the brain comes out to see: cerebral substance is pushed outward to make the essential ocular structure, the retina. In no other instance is this embryonic process the same; and the reason seems clear that in no other is such a procedure necessary; the mechanism could not be devised as in the other organs and senses with the crude and refractory materials at the disposal of the organismal artificer. It was only with its own highly differentiated and complex cerebral substance that the complex and differentiated retina could be constructed and kept in life and repair—as the food of the babe is part of the mother's own tissues. The number of medullated nerve fibers of the human optic nerve is about 438,000, the number of retinal cone cells at birth between 3,000,000 and 4,000,000. Noteworthy is the fact that the creation of the eye at birth is incomplete; the number of cones in the adult is double that of the babe. The number of retinal rods has been estimated as high as 130,000,000. Upon these hundred million rods and cones, as if upon so many bunched finger-tips of a blind man, is laid the warm picture, made by light, of the external scene, and the blind man sees, his crowded and extended fingers making, as it were, an eye.

The sensitive film of this living camera had to become a perfect mechanism of color-photography; had to be resensitized in an instant for a million pictures a day! All the adventitious peripheral structures—cornea, aqueous, crystalline lens, and vitreous, had also to be made and kept transparent without the usual red-blood corpuscles always necessary elsewhere. Such are a few of the difficulties encountered and overcome. Failure in any part inevitably threw out the individual, good in every other way, as unfitted to survive. If at the present time millions are thus excluded, what must have been the havoc in the animalian and savage past?

2. Adaptation to the environment and utilization of it by the organism was and remains impossible without the intermediate of self-motility. But this was likewise impossible without the prerequisite of vision to make the outside world known. Hence the synchronous and coincident development of the ocular and muscular systems. The accurate spacial and topographic representation of the objective world by the visual mechanism, and intimate, instant, and dominating guidance of all motor centers by the ocular picture, thus became primal necessities. There is scarcely an organ, surely no striated muscle, that is not directly or indirectly the servant of the eye. From animalian fight, shelter-seeking, and food-hunting, to civilization's latest cunning and devising there is an ever-increasing interplay of seeing and doing, until now vision seems to have vastly outrun execution. With every cerebral motor center awaiting, instigated by and obeying the guiding vision, how numberless the failures due to a hundred diseases and faults of mechanism! The present world of the sick, hurt, and prematurely dying are innumerable illustrations of the excluded unfit.

3. The optical axes, in the lower orders of the Mammalia, began with almost absolute divergence and proceeded toward parallelism through the progressing orders, until with the Simiae and Man there is perfect parallelism.* The large range of the axes in the Marsupialia (from 75° to 30°) is suggestive, especially when that of the Carnivora is found to begin the overlopping at about 50° and reach to within 5° of the perfect parallelism of Simiae and Man. The approach of parallelism may be looked upon as a kind of Ariadne clue through the maze of phylogenetic ascent. If we translate the approach towards parallelism, and its attainment by Simiae and Man, in terms of the struggle for existence, we gain a new insight into the profound significance of the lateral and of the forward-looking kinds of vision. The greater the self-motility and the fighting ability, the greater the approach of the visual axes to parallelism, the large and small Felidae being nearest that of the Simiae and Man. The difficulty in attaining parallelism is, of course, due to the necessity of great modifications, not only in the bones of the face, but even in those of the skull, the transplacing of the orbits, etc. The more divergent the axes the more gregarious, the more cowardly the animal. The common hare has 85° axes. What a vast, and astonishing influence, therefore, has this factor had in the entire evolution of the fit, the exclusion of the unfit, in animal psychology, in morphology, indeed, in every zoölogical inquiry! It seems to have been unsuspected.

4. In the same way the significance of the change in bodily posture from horizontality to verticality, effected in man, appears to have escaped proper recognition. It is man's most striking and differentiating characteristic, distinguishing him from the rest of the zoölogical world. Has it been effected without a long and mighty struggle, without profound influence upon the victors, without exclusion of great numbers of the vanquished? Concealed by the slow process of ages we do not see the profound changes that occurred during the passage from horizontality to verticality of body. Think of placing a habitually horizontally-bodied animal on his hind legs only, his body erect, and one has a picture of what immense modifications of morphology, physiology, etc., must follow before the abused animal, if he lived a thousand years, would see and act with any approach to our "natural" seeing and acting. The Marsupialia and other relics of the halfway accomplishment of verticality exhibit most significant traces of the sorry ill successes. They may be described as the forty-five degree zoölogical failures. It would have been quite impossible to create visual organs equally well adapted to alternating horizontality and verticality. Hence the comparative failure and absence of numerous species even of the 45° types. The marsupial pouch is a necessary device to meet an exigency caused by the constriction of the pelvic outlet, which is due to the induced massiveness of the bony pelvis, and this a result of body-weight resting upon these bones. The ovum soon after fertilization must be extruded at an early stage of gestation. In the kangaroo a special osseous support of the pouch is required—itself a hint of the failed struggle of the intermediating unfit. The primary necessity which drove the Simians

*See Johnson, *The Mammalian Eye.*

(and the Marsupials, also, for that matter) toward verticality was tree-climbing, for food-getting partly, but more to escape from enemies. But *pari passu,* one should not forget, came the required perfection of ocular function with parallelism of the ocular axes.

Out of many great changes consequent upon the assumption by Simians and Man of the upright posture I select several illustrating the difficulties and dangers encountered in fixing and making permanent the habit.*

When we medical men do not know the etiology of a disease we take refuge in the solemnly chanted words, *Diathesis, Neuropathic Diathesis, Neurasthenia, Hysteria,* etc. It may be said that in the human race spinal curvature is due to scoliotic diathesis. In a great American university, of about 1,200 Freshman examined by experts, 80 per cent. had lateral spinal curvature. The proportion does not probably differ in any occidental country where school children are taught to write in the way advised with us. These 60,000,000 of United States folk have, therefore, not only the scoliotic "diathesis"; they have the scoliotic fact. The support of two-thirds of the body weight by a single upright rouleau of ligatured bones, like that in the lumbar region, is an enormously expensive and hazardous proceeding, And yet accurate verticality might still be usually preserved if it were not for two ocular factors of mischief.† The morbid occidental writing-posture, due to ocular function and malfunction, together with some peculiar axes of astigmatism, are the active and sufficing causes of the great majority of cases of lateral spinal curvature. None may measure or calculate the part played by this astonishingly frequent scoliosis in the making of unfitness, and in swelling the morbidity and mortality rates.

Another cause and result (both peculiarly interwoven, as always in such proceedings) of permanent verticality of the body-trunk consists in the freeing of the front feet and legs from the function of walking and running, and making them into the manipulating tools without which *Simia* could never have become *Homo.* Immediately and synchronously in development came the evolution of sign-language, and of articulate language itself. The word *digit,* and the Roman numerals representing the fingers held up, are the living remains and evidence of the early stages of this evolution of the front foot, paw, and hand as a tool, and also of language-formation.

According to the admitted localization of the cerebral centers controlling muscular acts, the center for articulate speech is located upon one side of the brain, adjacent to the center for writing.. Articulate speech is a single not dual act, and hence its center could not in one person be bilateral. For the same reason neither could the writing center be double. Consequently the writing center and the speech center are close neighbors, located in one cerebral hemisphere, the left in the righthanded, the right in the lefthanded. The expert task of writing is carried out by the right hand, and because what is written is language (even now writing is correlated by the schoolboy with whisper and lip-motion) the contiguity of the centers in the *single* third frontal convolution is a necessity.

But there is now a new factor of great importance subtly introduced into the whole affair—that of a choice of one hand or of the other for special tasks. For certain delicate and expert ones the dextral hand was chosen in about 94 per cent. of men and women, in the other 6 per cent. the sinistral. In either case the less expert hand is the helper of or the holder for the other. Among animals there is no trace of such differentiation into right and left, because, of course, both front paws are equally and almost solely used for walking, etc. In the four-footed, horizontally-bodied animal, to the divergent right eye, looking to the right side, was allotted the task of seeing the world to the right, and particularly of placing the right front foot. To the similarly divergent left eye was given the left side to watch out for and the left foot to place.

There was in mammalian beginnings little forward-looking, because parallelism of the visual axes was ages ahead, and could not be complete until the front legs and paws could be relieved of locomotion, and, with the upright posture, put to manipulative uses. Such an animal blinded in one eye was thus quickly excluded as unfit. Ophthalmic disease and traumatism, of course, was more and more frequent as we go back to more remote and primitive conditions and habits.

With the vertical posture came righthandedness and lefthandedness, came parallelism of the optic axes, came downlooking, overlooking, outlooking, and forwardlooking, and the immense and sudden leap from monkey to man! Necessarily there were, besides those heretofore bespoken, a hundred vitally important modifications, extensions, and perfectings of function and structure which will long occupy the attention of future scientists. Of these we are here concerned with the ocular ones only; but what a vista is opened wherethrough we see the fittest to survive are often those only that are visually fit, and those excluded are they visually unadapted to the new conditions. Because, forget it not, the greatest perfection of visual function, from the day of assumed verticality, becomes the chief of all the agencies of progress. Ingenuity and intellect, speech, and writing, and printing, and language itself, could not follow without vision. The letters of the alphabet are conventionalized pictures, that is, ocular photographs; and memory, without which there can be no personality or individuality—memory and experience, are but a gallery of such photographs.

The latest complication and modification of visual function is a direct result of righthandedness; the eyeballs being placed 50 or 60 millimeters apart necessarily see two different pictures of an object. Therefore with delicate and dangerous tasks one eye must dominate. From the most primitive times the right foot or hand has been directed by the right

*The mystery, seemingly so insoluble as to paralyze even the questioner, of the descent of the testes stands as the *bête noir* of medical science. I suggest that the amazingly strange makeshift of extruding the testes from the pelvic cavity is due to the collapsibility of the seminiferous tubules, epididymis, and especially of the vas deferens. Even the most habitual horizontality of posture of any animal is often and somewhat continuously changed for a partial uprightness. The weight of the superposed viscera would prevent the amazingly long journey of the spermatoza through such thin collapsible tubules. In the subhuman Mammalia, therefore, the choked tubules would almost vitally endanger the propagation of the species, and in the habitually upright Simian and Man it would stop it. Cryptorchidism is accompanied by impotence. Every physician knows that the majority of all hernias are secondary to abnormalisms of the pelvic wall consequent upon the extrusion of the testes. Does not this great present-day vital expense to the community point to exclusions of other millions of the unfit in past ages?

†Helpful is the often overlooked fact that we spend one-third of our lives in bed—in the old horizontal position.

eye, the left foot or hand by the left eye. With the evolution of righthandedness, upon the right eye has devolved the duty of guiding in the more expert tasks. Hence the inevitable correlate of righthandedness is righteyedness (dextrocularity), and of lefthandedness it is lefteyedness. Indeed, I think that the precedent righteyedness forces the choice of the right hand as that for the more expert task, writing, sighting a gun, etc.* The infant chooses the right hand with which to reach out and grasp things because it is righteyed. All army regulations, uniform since Xenophon, cannot make the lefthanded soldier into a righteyed one. The question of righthandedness and righteyedness has been a mighty one in all history; all military life, drill, and maneuver, chivalry, single combat, the rule of the road, etc., etc., are commanded by it. All mechanics, tools, etc., must consider it well. Early railway locomotive building worked for years aimlessly at the unknown problem of righteyedness, until it was found out, none knew why, that the engineer must stand or sit on the right side of the boiler. Railway wrecks still occur because three double track roads pass to the left.

So advanced is the fixation of righteyedness that, in the righthanded, the right eye will retain its function of righteyedness despite a far greater degree of amblyopia than in the left, caused by late arising disease or ametropia. The left eye is far more subject to disease than the right, and is the one usually thrown out of use by ametropia, heterophoria, etc. There are, I suspect, a million Americans, whose right eye is the only useful one. Were it not that the nose hides from the right eye a considerable part of the world to the left side, it is probable that the trend toward a single or cyclopean eye would be greater than it is at present.† In the light of the localization of the speech and writing center, and of the origin of righthandedness, the blunder of the ambidexterity-monger is as maleficent as may be easily imagined. Every lefthanded child taught by him to write (and that is all he tries or is able to do) with the dextral hand is thereby sadly and permanently injured.

5. If one is able to fix the visual axis of one eye, without movement or winking, upon an illuminated object, it soon fades out and disappears. The sensitive film, the retina, can hold the image but a second or two. Constant change of stimulus, of the scene or image, variation of light and shade, etc., are necessary to retinal resensitization. The fact points to the fifteen mechanisms I have described which bring about this change of place, of stimulus, and of regenerating shadow.‡ Observation shows that the lower mammalia have eyes inferior to man in visual power. The widely opened pupils and lids prove this fact even if other evidences were not manifest. All birds, nocturnal prowlers, etc., must see upward and widely about, so that the shading mechanisms of the human retina are necessarily absent. That the numbers of rods in the adult are twice those of the infant suggests far greater complexity and responsiveness of the visual function of man as compared with that even of the higher animals. It also prophesies further progress. But the shading mechanisms, in their totality, so necessary in man, are themselves demonstrations that in the ascent toward humanization and civilization the individuals superiorly equipped in these respects won in the struggle over those with less protected retinas.

Winking excepted, the chief of the human shadowing mechanisms is the position of the border of the upper lid at the upper edge of the pupil, followed by its instantaneous descent over the pupil in every act of winking. While hovering above the border it is shading, when dropping over it, it is wholly blackening the retina. Its position is a consequence of the vertical position of the body and head, to shield the retina from the unused light above which would otherwise flood it with stimuli and thus drown photographic definition.

This inobviable necessity of the habitual placing the upper lid at the upper border of the cornea of vertical-bodied man brings with it a sad new evil, less pathogenic than would have been the excess of light, it is true, but still of enormous disastrous results of civilization. It is the chief cause of astigmatism. The cornea is warped by the pressure of the lid and one radius of its curvature is rendered greater than that at right angles to it. The retinal image of an astigmatic cornea does not therefore represent the true conditions and topography of the external world. The cerebrum is the organ of the inherited average of all past experience of approximately perfect visual images. The widely variant and morbid retinal stimulus passing through the 400,000 optics nerve fibers to all parts of the cerebral switchboard, meets the infinitely complex but perfectly normal, receiving and relaying mechanism. Resultant abnormalism of sensation, as to shape, color, accuracy of topography, etc., confuses the sensorium, and makes external action, based always upon vision, hazardous and ill adapted for the act and for the individual. The individual must succumb, the race must persist. It is all a clear example of the truth that the body is really a part of the environment. Compounded with the other forms of ametropia as it usually is, we have the greatest of all environmental limitations to the progress of civilization. Almost every human eye has little or much astigmatism—there is not an optically or mathematically perfect pair of eyes in the world—and a small defect of shape may be more harmful and unfitting for the struggle for existence than the greater ones. The only miracle of ingenuity impossible for the ocular mechanic seems to be to make an eyeball true to within 1/200 or 1/300 of an inch. That fault of shape or measurement is constantly excluding millions from work in late social development, and differentiation of function.

I beg you not to think or characterize this as the visionary imagining and exaggeration of specialism or of ill-balanced judgment. The reception of dis-

*I have had two left-handed patients who, compelled to shoot from the right shoulder, could take aim only when they depressed the right eye below the gun-level, and sighted with the left eye.

†In reference to the disadvantage of a high nasal bridge in man, it should be noted that Oriental types have a higher wall between the eyes than the Teutonic races, who are now the chief carriers of an advancing civilization. In the statues of the classic Greek and Roman sculptors the line of the nasal crest joining the tip of the nose and the forehead is a straight one. The Jew of to-day illustrates the same inheritance, or, indeed, that from a more remote ancestry in which the bridge bowed forward or outward. With us, instead, there is a marked depression between the eyes, which will probably increase, and thus will be avoided some of the disadvantages of the trend toward monocularity.

‡In birds the pecten, I suspect, unites in itself the most of these mechanisms, the large floating mass of waving vessels, with every movement of the bird's head, securing shadowing of one macula, while exposing that of the other eye. Birds, nocturnal prowlers, and those animals with habitually widely opened lids have no astigmatism and thus have this compensation for their less sensitive retinas, etc.

coveries, medical or purely scientific, of the past warns us that the greatest advances often spring from overlooked little things, and that prejudging is unsafe. Even as a military organization the German nation has far less validity than is necessary, because of myopia. The greatest ocular handicap after astigmatism is the hyperopic eyeball, well adapted for old-world life-tasks, but most ill-fitted for the inordinately demanded near-work of civilization. Astigmatism is the chief cause of myopia, and of cataract. Astigmatism is unavoidable, but all its effects may be easily avoided. Accommodational failure, or presbyopia, is also inevitable, but its evils may also be circumvented. Handed down as a tradition of the past ages, an absurd premature senility and a long drawn out useless old age have become so customary that one may hardly recognize that both are the needless results of unnecessary eyestrain.

The catalogue of ills and the exclusions of the unfit—because of ocular malfunction, are by no means ended. The president of the *British Medical Association* officially emphasizes the testimony of hundreds of other careful scientific medical men that vast numbers ("millions," he says) suffering with incapacitating headache, produced by eyestrain, have been relieved by spectacles. The Governor of Massachusetts goes much further in his inaugural address, and a famous surgeon of New York City says he avoids the majority of abdominal operations by sending patients to oculists who cure them with glasses. The great majority of the diseases of the world's sick and prematurely dying began in functional disease, which is of course simply abnormal physiology. The larger number of aberrant physiological processes are directly or indirectly due to slight imperfections of measurements and shape of the eyeballs. Eventually they phase themselves into those mysteries of medicine called migraine, headache, sick headache, functional diseases of the digestive organs, lateral spinal curvature, kyphosis, nervous and mental diseases, such as insanity, much criminality, hysteria, neurasthenia, epilepsy, even suicide. There is an abundance and a growing mass of testimony that these diseases are very largely the consequences of morbid ocular function. Only the healthy are admitted to the future phylogeny; the diseased are unfit. It is easily possible to eradicate the diseases caused by eyestrain, and when the opportunity is realized, the number of medical men, colleges, and hospitals will be reduced by more than a half, the morbidity-rates and mortality rates equally decreased, while the number of those endowing the future will be correspondingly increased.

THE MEDICAL MANAGEMENT OF DEGENERATE CHILDREN.

By ROBERT H. PORTER, M.D.,

CHICAGO.

At the present time backward and delinquent or truant children are receiving more careful attention than ever before. The discussion of this important subject, from the educational and social points of view, has been the means of accomplishing a great deal of good for defective children. Classes are so arranged now, in both the public and private schools, that a defective child can receive all the instruction he can appropriate and utilize, without the great wear and tear which an effort to keep up with his more fortunate and better endowed companions would produce. In an effort to benefit this most unfortunate class, it seems, in some cases at least, that the benevolent pendulum has already swung too far, so that now more money is being spent in an effort to educate some of them than the ultimate results would justify.

The educational side of the problem is well equipped in all large cities, and whenever a boy becomes an habitual offender and is no longer amenable to his home and school authorities, he is sent to a school of reform. Some of these are located on farms, where the boy has certain hours every day for study and the balance of the time is spent in working on the farm; while others have a manual training school attached, where part of the time is spent in learning some useful vocation for which he is best adapted. By such means great good is often accomplished and many go out from these schools making useful citizens. While the educational side of this great subject is important and must by no means be neglected, yet the question of primary consideration is one of disease.

Fig. 1.—Baxter at the age of 18 months.

The delinquent child is a half-brother of the backward child. In fact, many backward children become delinquent because of their own mental and moral deficiency. Beginning with the feeble-minded child that is dull and backward, just a little below the normal, extending down through the delinquent, the imbecile, and the idiot, all of these children have something in common; a morbid bias which has caused them to depart from the normal.

Most of these children, in addition to their mental deficiency, have physical signs of impairment known as the stigmata of degeneration. While each individual differs, more or less, in the morbid, as well as in the normal development, yet through this bondage of degeneracy they are related to one another to a certain degree, as they are not to the rest of the population. Now this condition of degeneration is the effect of disease, and if, under the proper medical management, this diseased state could be removed, many of these children would be restored to the normal, others sufficiently improved to learn some useful vocation so as to prove self-sustaining, while some of the idiots could be benefitted to such an extent as to learn to talk, walk, and be able to dress, feed, and take care of themselves.

The best authorities agree that morbid heredity is generally the cause of mental deficiency. In other words, that a morbid inheritance is the cause of this form of degeneracy in most, if not, all cases. The writer, in the study of some of the other forms of degeneration, arrived at the conclusion that chronic toxemia is the cause of the first departure of the individual from the normal, and from this chronic toxemia the various forms of degeneracy may sooner or later develop. The chronic toxemia may be either mental, chemical, or microbic in origin, or most probably one or more of these in combination with other morbid conditions and an unfavorable environment. While it is well known that a certain infectious fever is caused by a definite or specific germ, yet when the patient is carefully examined, he is found to be suffering from a mixed or multiple infection. So it will no doubt prove to be true that degeneracy is the effects of a chronic multiple infection. The toxemia may remain latent for a long time, slowly impairing the nutrition and vitality of the brain and nervous system, with a marked tendency to the development of the neuropathic diathesis. And it is from this diathesis that the various nervous maladies may develop. Just what kind of nervous disease may develop from the diathesis depends largely on the life, habits, and environment of the individual. The condition of the patient will vary greatly according to the intensity of the toxic impressions, his vital resistance, and whether his environment, mode of life, etc., tend to increase or counteract the morbid tendencies; and also as to the part of the brain and nervous system most affected. No doubt, in many instances the individual toxemia serves only to start a neuropathic diathesis that may show itself in some mental or physical defect in the offspring. But a vicious and intemperate life, with excessive drinking, smoking, or any of the various drug habits, will very much intensify the degenerate tendency.

Fig. 2.—Buster at the age of 7 years.

Nature, through the law of the survival of the fittest, endeavors to eliminate the unfit, the degenerate. First, and the method most often used, is where favorable conditions are intelligently directed, and either the individual or his descendants are restored to the normal. This represents the more vigorous among the degenerates, and those among the well-to-do, when all science and all knowledge are made subservient to the welfare and benefit of this greatly afflicted class. Thus under favorable conditions degeneration is eliminated through the propagation of the race. And, second, is where ignorance and poverty combined with unfavorable conditions serve to so intensify the degenerate tendency as ultimately to result in extinction.

It is not at all surprising that the defective classes should produce degenerate children, but it is also true that a temporary toxemia in parents may start a degeneration in the offspring that may be both destructive and farreaching in its effects. Thus it can be seen how there may be defective children among the well-born and the well-to-do; for the degenerates are by no means confined to the defective classes. If they were so limited, then the problem could be much more easily handled.

Then, again, in a certain sense, the degenerates may be regarded as among the by-products of civilization, and with the rapid progress being made by modern civilization the waste materials must of necessity be very large, and this is confirmed by the great increase in the various degenerate classes in all civilized countries at the present time. In the present state of development, it would be impossible to secure the necessary laws to prohibit the marriage of the unfit. And even if there were such laws, and they were rigidly enforced, this would not perceptibly reduce the number of degenerates. Such measures would be ineffective and relief is not to be sought in that direction.

If a magician could wave his wand over one of our large cities and at once restore all the degenerates to the normal, but in all other respects leave the life and other conditions just as they are now, then the first generation would produce an abundant supply of degenerates among all classes of the population, for the elements of degeneration are diffused through the people without any respect of persons, either of high or low degree.

The strain and stress of modern civilization serve to intensify the neuropathic diathesis, especially in all the large cities, where the atmosphere is at all times charged with impurities and toxic germs, the water often polluted, and the food more or less contaminated or adulterated. Then, many of the amusements and diversions at night, with intemperance in eating and drinking, frequently consume more vitality than the daily duties. From these conditions it is not at all surprising that there should be so many nervous maladies.

The chronic toxemia may often combine with other morbid conditions, so that each serves to intensify the other to such an extent as to cause nutritive deterioration and even degeneration in the various organs of the body whose structures were once well organized. This condition of degeneration is often seen in the brains of the chronic insane and the epileptic.

Now, these morbid conditions may have such a detrimental influence over the nutrition of the infant and the young child as to cause an arrest of body

and brain development, either one or both, in varying degrees. The arrest of brain development causes mental deficiency and that of the body produces the stigmata of degeneration. The nutrition of the brain and body is so intimate that whatever impairs the one is very likely to affect the other also, and this is true to such an extent that generally children with mental deficiency are poor in vitality and below the average both in size and stature. But there are some notable exceptions to this rule.

Degenerate children make feeble units, and they easily fall victims to the various infantile maladies and often have convulsions, Saint Vitus' Dance, or epilepsy. Instability is as characteristic of their vital processes as it is of their moral or mental qualities. It is the intensity in the expression of the mental and moral perversions that distinguishes the degenerate from the normal child, just as it is the intensity of expression that distinguishes the insane from the sane.

In these children with mental deficiency there may be an arrest of development along certain lines, with perverted activity in some and excessive activity in others. Whatever they attempt to do is done wrong. They are normal in nothing. The ability and resources of a degenerate child to create and maintain a reign of terror, anarchy, and destructiveness has to be seen and experienced to be fully appreciated.

Dr. A. F. Tredgold of London is at the present time the highest authority on mental deficiency, and he recently said: "There is no drug which has the slightest direct or specific influence upon primary mental deficiency, and, we may safely assert, there never will be. Considering that this condition is the outcome of a neuropathic diathesis, due in many cases to generations of antecedent disease, we can no more hope to relieve it by medicaments than we can hope by such means to transform the worn-out tissues of age into virile ones of youth, or to restore life to the dead." Dr. Tredgold believes all that can be done for these unfortunate children must come to them through environment, training, and education. While these are important aids, and must never be neglected, yet in all conditions of disease they must of necessity be secondary to the necessary therapeutic measures.

Now the condition of the defective child, whether backward, delinquent, imbecile, or idiot, is the effect of disease, and if ever he is to be restored to the normal it must be done through the proper medical management. As the doctor has well said, the deplorable conditions associated with mental deficiency are the effects of antecedent disease, and yet it is immaterial whether the neuropathic diathesis has existed for one or many generations; it never becomes normal to the individual, but always shows the persistence of the morbid elements. The neuropathic diathesis is due to physiological chemical defects in the nutrition of the brain and nervous system. Nature is all the time trying to restore and maintain the normal. Now if the proper chemical measures are used to correct these defects at the right time and in the right way, then many of these defective children can be restored to the normal, while others can be sufficiently improved to be independent and take care of themselves.

What are the indications for medication? This deplorable state of mental deficiency is due to antecedent toxicogenic conditions. The patient is below normal in vitality and vital resistance, the temperature is often subnormal, the circulation poor, and the nutrition defective. Stimulating tonics, antiseptics, and eliminatives meet the general indications in many cases, but if there are complications of either epilepsy or mania with a tendency to violence and destructiveness, sedatives are needed. Many of the secretions of the body are antiseptic or germicidal in character, and when defective they can be stimulated by the proper chemical measures. It is the chemical correlation of the secretions of the various organs of the body that keeps up functional activity and at the same time maintains normal nutrition. In the defective child there is an arrest of development with perverted nutrition in one or more of the vital organs.

The biologists tell us that by giving the extract of an organ, either by the mouth or hypodermically, as the case may require, not only the functional activity of the organ may be very much increased, but this will assist in building up the structures of the organ itself. This adds to the present resources the benefits of the whole field of organotherapy. Along this line of investigation the administration of the thyroid gland has been most studied and its effects are best known. And yet it is said that the chemical constituents of the gland will vary with the age of the animal and the season of the year when slaughtered, the winter-killed containing the most iodin.

Continued clinical study in the administration of the thyroid to defective children will be required to clear up some obscure points, for at the present time while some of these patients are very much benefited by it others are not, and in some cases the use of it is contraindicated. When properly studied other organic extracts will no doubt prove equally beneficial in many of these cases.

The writer had devoted many years to the study and treatment of defective children before the present knowledge of organotherapy was developed, and as many measures then used had proven very beneficial he has continued to use them in connection with the newer resources. "Prove all things and hold fast to that which is good" is a valuable precept in medical things as well as spiritual affairs. Let us see what is the effect when these principles are applied to the individual patient. The first cases reported will be those of three idiotic children:

Case I.—On June 18, 1908, J. C. brought his nine-year-old daughter to my office, carrying her in his arms. Her body and limbs were well developed and well nourished and she was about the average in size for her age. Her head was normal, both in size and shape, but the expression of the features was idiotic, and I could not tell if she heard or comprehended anything said to her in my office. Her cry had the peculiar tones of an idiot; it is so characteristic that when heard you can always tell that it is the cry of an idiot, whether you see the child or not. His wife had been dead for some time and this child was cared for by one of his daughters, and at home she could hear and understand, but only to a very limited extent, what was said to her by this sister who took care of her. She had never made any attempt either to stand, walk, or talk. She could sit at the table while being fed; she ate and slept well enough and was content to remain quiet in an easy chair or on the bed, wherever she was put during the day. The various organs of the body, as well as could be determined under the circumstances, were in good condition and their functions were fairly well performed.

After a careful study of her condition she was

regarded as a low grade idiot just above the deaf mute, and that her deplorable state was due to defects in the physiological chemistry of the brain. As far as could be determined the only defects were in the nutrition and organization of the brain structures. As her morbid state was regarded as the effects of antecedent toxicogenic conditions, she was given the thyroid extract with antiseptics, and these were modified from time to time as needed. In a little while she began to improve, and in six months she could stand and walk across the room alone, could talk well enough to be understood by the family, and had very good use of her hands. During this period she has had two attacks of rheumatism that retarded the improvement. The indications are that she will improve more rapidly in the future than she has up to the present time.

Cases II and III.—On January 10, 1908, Mr. and Mrs. K. brought their five-year-old son to my office. He was well grown and well nourished, somewhat above the average, and his head was too large even for his body; not actually hydrocephalic, but more like what is sometimes seen in epileptic children. He could not stand alone and had never walked or talked. He could hear, but his comprehension of what was said to him was very limited. The expression of his features was idiotic in character and the lower part of his face was too full and heavy. A physical examination of his head showed parietal and occipital tenderness. Their nine-year-old son, left at home, was in a similar condition, only more helpless. Instead of being well nourished he was frail and delicate; his appetite and digestion were poor; his limbs small, rickety, and cold. His complexion was pallid, the expression of his features idiotic, and his comprehension was about the same as that of the younger boy. The oldest one was very timid and had a great fear of falling, it being difficult to make him try to stand up, even when supported.

In each of these cases there was an arrest of brain development, and in the case of the older boy there was an impairment of nutrition of the body as well. After a careful study of all the conditions a definite line of medical management was adopted, and the first indications of improvement were physical in character. The older boy soon began to show an improvement in his appetite and digestion and commenced to gain in strength and flesh. There was a corresponding change in his complexion and expression, and there was also a favorable change in his mental condition. In the younger one the first change noticed was in his expression, and in a little while he began making efforts to walk and talk. In six months this boy could walk about the house, go in and out of doors, take care of himself, and talk plainly enough to be understood. In the same time the older boy became the picture of health, but improved less rapidly in walking and talking than his brother.

Just about this time the mother broke down with pulmonary tuberculosis, and as they lived out of the city the treatment was suspended with the promise of taking it up at a later date. A recent report said the younger continued to improve slowly, but the older remained stationary when the treatment was stopped. Each one of these boys was given thyroid tablets, and I think with marked benefit, and also such tonics and antiseptics as the peculiarities of each indicated, with stimulants for the abdominal secretions, not as a laxative, but just to maintain the secretions up to or a little above the normal.

Of all the complications met with in mental deficiency epilepsy is the most frequently seen, and at the same time it has been regarded as very unfavorable for the patient. In fact, it is considered one of the most hopeless forms of the disease, for the conditions that produce epilepsy with mental deficiency will in the end very likely cause dementia also, and this heretofore has been regarded as an utterly hopeless state. The further aim of this paper is to show that there is a brighter side to this picture, and also to indicate that the outlook for these patients in the future is much better than it has been in the past, as the following cases will very well demonstrate:

Case IV.—June 10, 1907, S. L., aged ten years, a demented epileptic, was brought to my office. She was having from eight to ten spasms every day, the attacks occurring both day and night. She was very frail and delicate and so feeble that she could hardly walk. The appetite and digestion were poor, and owing to the frequency and severity of the attacks she was confined to the house all the time, and to the bed most of the time. She did not comprehend anything that was said to her while in my office and had not spoken a word for three years. When six years old, while going to school, she began to have light epileptic seizures at irregular intervals. As these became more frequent and severe she had to stop school, and after the attacks had continued for about a year she stopped talking. In this case there was evidently an impairment of nutrition of the brain structures in addition to that causing epilepsy, for otherwise she would not have succumbed so rapidly to the epileptic seizures.

One of the greatest difficulties encountered in the treatment of this patient was due to the fact that her parents were Polish. Her mother could only comprehend a very few simple words spoken in English and the father was not much better in this respect. He was a carpenter with irregular employment and limited means. You can readily understand that ignorance and poverty produce an unfavorable environment for one of these patients and may often form a bar to successful treatment. While part of the time there was an interpreter, yet the mother could not intelligently carry out the instructions. The patient was given the bromide treatment and the attacks were arrested at once, but during the first year's treatment there was an occasional spasm due to inefficient management. Yet under the circumstances her improvement was remarkable. She gained rapidly in strength and flesh, in a few months began trying to talk again, and by the end of the year she could talk fluently enough, but not intelligently. The children she played with during the day talked English, while her parents at home only spoke in Polish and she was confused between the two. Soon after this time, however, and to improve the conditions, she was started to school, and under the instructions of the teacher in a little while could talk clearly and began learning very rapidly. The present improvement indicates that she will be permanently restored in due time.

Case V.—December 27, 1907, W. H., ten years old, was brought to my office for epilepsy, with which he had suffered for eight years. At the time he was having the attacks in series, usually five to ten spasms a day for two or three days, then a free interval of one or two weeks. The convulsions occurred both day and night. There was an arrest of mental and physical development; he was two or

three years below the average for his age and had always been frail and delicate, with appetite and digestion poor; bed wetting very bad. When eight months old he had several spasms with an attack of indigestion. Then about a year after this time he began to have little sick spells with choking sensations and there was a noise in his throat as if he were trying to swallow something. This condition recurred several times a day at irregular intervals. They proved to be light *petit mal* seizures, but a correct diagnosis was not secured until the second dentition, when epileptic convulsions developed.

The attacks gradually increased in severity and frequency until the above date, when he was given the bromide treatment, with an arrest of the spasms. While at the end of five months' treatment there had been no return of the convulsions, yet there was no improvement in his general condition, and by this time he was suffering so much from the toxic effects of the remedies, with several ulcers on both legs, that the bromides were discontinued and he was given brometone and chloretone, with the thyroid extract. The change in the adjustment of the remedies proved very beneficial and he soon showed an improvement in appetite and digestion, began to take on strength and flesh, and during the past eight months has grown six inches in height and has been going to school regularly since last September, something that he had never been able to do before. The indications are that he will be entirely restored.

Case VI.—June 10, 1886, Mrs. H. came to see the writer with her son Willie, aged twelve years. When seven years old he began to have little sick spells; he would have a vacant stare and seem dazed for a moment. Whatever he was doing at the time he would stop for an instant and then go on just as if nothing had happened. The seizures gradually became more frequent, returning many times every day, so that when ten years old he had to be taken out of school. Not only did the attacks become more frequent, but occasionally one would be prolonged, lasting several hours, and once continued for twenty-four hours. In this state when unmolested he would sit quietly and take no notice of those about him, but if aroused and asked questions he would answer intelligently. His condition while in this state was similar to a mild form of trance. There was an arrest of both mental and physical development, and at the time of his first visit he was having from two to three hundred of these light seizures daily, always worse early in the morning and during the forenoon. Under the proper treatment the attacks were immediately reduced to ten or fifteen a day. Then as he improved they gradually subsided, and he has now been well for more than twenty years. From a mental and physical degenerate, when the morbid bias was removed, he improved so rapidly that in a few years he became both mentally and physically superior to his parents, as well as to the other members of the family, and stood head and shoulders above them all.

Case VII.—September 1, 1886, Mrs. O. brought her ten-year-old daughter to the writer for a very complicated form of epilepsy with which she had suffered since infancy. At first she had infantile spasms, which after a while were recognized as true epileptic seizures. These would occur at irregular intervals, then she would have periods of irritability and perverseness instead of the spasms. She gradually grew worse and the seizures became complicated, so that she would have several spasms daily for a week, followed by a free interval. Then she would become delirious and for several weeks would pass through various forms of mania; at one time be violent and destructive, with homicidal and suicidal tendencies; at another, very profane, using such language as it seemed impossible for her ever to have heard. Then she would have a period of pyromania with a desire to set the house on fire and burn herself and everything else that she could. On one occasion when the delirium continued for eight weeks, the most prominent of many visions which she had were those of Indians and little devils. But she was always more afraid of the Indians than anything else. One day she said, "I am going to have a devils' funeral," and after that she was never troubled with the little imps. After another interval of relief, in which she would be fairly normal, she would pass into a condition of double consciousness—have two distinct and independent mental states, which would alternate with each other every two or three days. While in either she would know her family, behave fairly well and remember well enough all that had transpired in the last similar mental condition, but nothing that occurred in the other mental state. Of this she could tell nothing. This double consciousness would continue for two or three weeks, then subside, to be followed by some other morbid manifestation; always some change, never the same thing twice in succession. This great variability made the case an intensely interesting one. However, she was regarded as an unstable, degenerate epileptic. The spasms were arrested first and all the other morbid manifestations gradually subsided, and she made a good recovery.

One of her brothers was also an epileptic. He was treated at the same time and has now been well for more than twenty years.

For some years I have been the medical director of a colony for degenerate children. It is located on a small farm and is maintained by voluntary contributions. The colony is conducted for degenerate children only. No normal children are taken care of. Owing to the character of the children they are not sent out into homes, but are kept in the colony until they are grown. There is a school on the premises, and the boys work in the garden and on the farm and at the same time learn some useful vocation so as to be self-sustaining when they go out into the world, which they usually do when about eighteen or twenty years old.

The girls help about the housekeeping and assist in taking care of the younger children, and usually remain in the home a little longer than the boys. When a child is first received at the home it is given careful nursing and suitable feeding, so as to have it well cared for and well nourished. When a child shows a slight deviation from the normal it is subjected to a period of careful training to see if it is only a childish whim and can be corrected in this manner, or if it is the first indication of an underlying bias, perversion, or some of the early manifestations of degeneracy, before any medical measures are adopted. In many instances the vicious and degenerate tendencies begin to show in a marked degree by the time the child is two or three years old, and in some cases even before this time. Two or three cases will be selected from the colony.

Case VIII.—Buster was brought to the colony when about eighteen months old, and the first pic-

ture was taken soon after. He was the offspring of insanity on one side and crime on the other, the origin of the most dangerous class of criminals. The first picture, taken in connection with his disposition, indicates a criminal degenerate, a murderer in the making. He had an ungovernable temper, was fearless, cruel, and destructive to a remarkable degree, and had a perverted appetite with insatiable cravings. For a long time Buster was a terror to the other children, for when in a rage it seemed as if he would try to kill some of them. He was a mental and moral pervert, a little demon of destructiveness. Enuresis is often seen among defective children, but he was the worst case that I have ever encountered. He was wet all the time, both day and night, and this proved to be a distressing and difficult condition to correct. After a careful examination a line of treatment was adjusted at once, giving him sedatives, antiseptics, and eliminatives, and these were varied from time to time as needed.

In all degenerate children the first indications of improvement following the proper medical management are physical in character. Buster has now been under regular systematic treatment something over five years, and there has been as much, if not more, improvement in his mental and moral condition as there has been in his physical, as shown in the second picture. As he still shows vicious tendencies occasionally, especially along the lines of destructiveness, he will be kept under treatment until all of the morbid and defective manifestations have been entirely eliminated, for as the morbid elements and tissues are removed nature restores the normal. Now at seven years old he is very industrious, a great worker, and is doing well in school. His environment and training have assisted very greatly in his improvement, but they are secondary to the medical treatment. The normal nutritive processes of the brain are chemical in character and any marked impairment of the nutrition of the brain structures shows some chemical defects, and chemical defects are only corrected by the proper chemical measures.

When I first became associated with this colony there were ten youths between twelve and fifteen years of age, who had been living in the home for ten years, and they had had the full benefit of the environment, education, and training during all these years, and yet each one showed in a marked degree some of the mental, moral, and physical signs of degeneracy. The proper treatment was adjusted for each; they were kept under observation for five years. During this time all morbid manifestations were gradually eliminated, and since going out into the world they have all made good men and women and have proven self-sustaining. One case will be sufficient for the purpose of illustration:

Case IX. J. M. was brought to the colony when two years old. His father, now dead, was a member of a gang of railroad train wreckers and robbers and a criminal degenerate of the worst type. His mother unknown. The boy showed criminal degeneracy very early in life, and was regarded as the worst boy they ever had. He had been in the colony ten years when the writer became associated in the work, and soon after this a careful examination showed an arrest of mental and physical development. He was two or three years below the average for his age, with marked perversions of a dangerous character. He was utterly fearless, with intense ego-mania, dictatorial, cruel, destructive, and subject to periods of violence, when he was dangerous to those about him, especially the younger children. He was a petty criminal to the extent of the colony opportunities, stealing and hiding many things for which he could have no use, and was so perverse that he would often tell a falsehood when the truth would have been more beneficial. He was cunning and crafty, but disinclined to school work. During the first year's treatment an improvement in his condition began, at first physical in character. He grew taller and there was a corresponding change in the shape of his head and face, and the expression of his features from being morose became brighter and more animated. After this there was an awakening of his mental faculties with a complete moral revolution; he became very ambitious to learn, spent all of his spare time in reading and studying, and declared that he was going to be a preacher of the Gospel, as his grandfather had been; but of this latter fact he did not know. For some time following this there was a raging conflict within. For a while he would be able to practice self-control and cultivate his best mental and moral qualities; then the criminal demon would gain possession of him and for a short time he would have a period of violence, becoming cruel and dangerous. All this time he was treated in a scientific manner for his criminal degeneracy, and slowly but surely it was being eliminated. After being under treatment a little over five years he had a very favorable opportunity of going out to work, and as he was so near normal by this time, it was thought best to give him the benefit of it. The result has been most satisfactory. He has not only been self-supporting, but is helping to take care of some dependent relatives. He is a good mechanic, thrifty and industrious, and always has some money in the bank. It is now seven or eight years since he left the colony. This patient, and the same is true of his companions in the colony, had the same environment and training before as after adopting the medical management.

Owing to the variety, intensity and number of wayward and vicious emotions in degenerate children they require a more rigid discipline and careful training than do normal children. Notwithstanding the fact that these boys and girls had lived an out-of-door life on the farm, had the best quality of food carefully selected, daily religious instruction and were under the constant care and supervision of a most efficient disciplinarian, making a very favorable environment, and these conditions had existed for ten years during the period of greatest growth and development, yet everyone of them showed the mental and physical signs of degeneracy. These indications of degeneracy were due to chemical defects in the nutrition of the brain and nervous system, the effects of antecedent toxicogenic conditions, and they were not corrected until the proper chemical measures were used. While training and a favorable environment are important and necessary, yet the results here show that for degenerate children they are secondary in comparison with the proper therapeutic measures; and, on the other hand, the best results are only to be secured when the two are combined. The records of the colony show that environment, education, and training are not in themselves sufficient to correct the moral perversions of degenerate children, and without the proper medical attention these perversions will sooner or later develop into criminal acts.

6200 Monroe Avenue.

SURGICAL TREATMENT OF DIARRHEA.

WITH

A DESCRIPTION OF A NEW CECOSTOMY WHICH PERMITS FREE IRRIGATION OF BOTH THE SMALL AND LARGE INTESTINE.*

By SAMUEL GOODWIN GANT, M.D., LL.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE RECTUM AND ANUS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Were you to ask the average medical practitioner if he could cure chronic diarrhea by dieting, medication, and rest in bed, on the spur of the moment he would reply in the affirmative. On the other hand, if you were to give him sufficient time to deliberate, and then ask him to state the percentage of permanent cures effected by such treatment, he would most likely be more conservative and say that he could usually diminish the evacuations and sometimes temporarily arrest the diarrhea, but that he could not recall the exact percentage of permanent cures obtained by the therapeutic measures named.

Personally, I doubt if more than ten per cent. of the persons suffering from chronic diarrhea are curable by means other than through bowel irrigation as practised through the anus, or from above through the appendix or cecum. Of those who do not respond to direct treatment of the colon, the cause of the trouble in a number of cases is located in the small intestine, stomach, liver, or pancreas. When diarrhea originates from disturbances located in the organs higher up, sooner or later the mucosa of the colon becomes inflamed or ulcerated as the result of irrigating discharges which must pass over it. Consequently, it is of the utmost importance to differentiate between gastric, enteric, pancreatic, and hepatic diarrheas as those caused by lesions situated solely in the large bowel. It is also necessary to treat the inflamed and ulcerated colon in these cases after the disease situated in the other organs has been corrected; otherwise the diarrhea may be expected to continue.

Chronic diarrhea, in the vast majority of instances, is caused by some one of the many forms of catarrhal or ulcerative colitis, and the lesions which are responsible for the diarrhea can be inspected through the proctoscope or the sigmoidoscope, but when the disease is located above the sigmoid flexure it cannot be discovered by instrumentation. To clear up the diagnosis in doubtful cases, the bowel should be thoroughly washed out daily with some stimulating antiseptic solution to determine whether the lesions are confined to the large bowel or involve other organs. When the ulcers are limited to the colon, effective irrigation will materially diminish or completely arrest the frequent stools, but when the diarrhea is caused by disturbances of the small bowel, stomach, liver, or pancreas, the manifestations arising from autointoxication will be improved in this way, but the effect upon the diarrheic condition will not be so marked, because the medication does not reach the principal seat of the trouble.

In some instances a macroscopical or microscopical examination of the gastric contents and the excreta will enable one to determine whether the diarrhea was caused by involvement of the stomach, liver, pancreas, or intestine, and, further, when the bowel is found to be the disturbing factor, it will aid us to find out whether the disease is located in the small bowel, in the colon, or in both.

Frequent evacuations and rectal tenesmus often result from a cancer, benign growth, stricture, angulation, invagination, volvulus, abdominal tumor, or disease situated in the ovaries, tubes, uterus, bladder, or prostate, which presses upon or narrows the lumen of the bowel; hence, before making a positive diagnosis in cases of chronic diarrhea it is necessary to determine whether or not the frequent stools are due to an obstruction located in the large intestine.

Chronic inflammation of the mucosa may excite frequent discharges of mucus, but it does not greatly increase the number of fecal evacuations; but when the mucous membrane becomes ulcerated, the frequency of the stools is immediately increased. When the ulcers are small and far apart, the daily movements will be few; on the other hand, when they are multiple and of large size, the evacuations will be frequent. If chronic diarrhea, as I believe in the vast majority of cases, is induced by ulcerative lesions situated in the colon, then it appears to me that the usual method of treating this complaint with drugs, internally administered, is wrong and should be discontinued.

I concede that medicines judicially used may lessen the number of evacuations and sometimes arrest a violent attack of acute diarrhea by drying up the secretions and quieting peristalsis, but in the chronic form I have rarely known them to effect a permanent cure, but have, on many occasions, witnessed a return of the diarrhea as soon as the effects of drugs had worn off.

Chemicals, like bismuth, chalk, opiates, intestinal antiseptics, mild astringents, and other remedies so frequently prescribed for the relief of this condition are harmful to the system in many ways; patients frequently become addicted to their use, and bismuth balls (enteroliths) often form and cause irritation or complete obstruction. For these reasons and because of the ineffectiveness of medicines administered by the mouth in healing lesions responsible for the frequent evacuations, they should be discarded in the treatment of chronic diarrhea, except when, for any reason, direct treatment of the bowel is refused or found impracticable.

In many individuals who suffer from diarrhea induced by chronic colitis, the lesions are more manifest in the rectum and sigmoid, and require topical applications of silver nitrate or pure ichthyol to make them heal more quickly while the irrigating treatment is being carried out. Much better results are obtained in the handling of this class of individuals when they are given to understand at the outset that several weeks' treatment will be necessary to effect a cure, and they must come to the office regularly and faithfully carry out the physician's instructions while at home, because nothing can be accomplished when the patient drops in to see the physician at his own convenience.

I have succeeded in curing a great many persons suffering from chronic diarrhea without an operation, by the daily irrigation of the bowel with different solutions. In fact, nearly all cases could be cured in this way if the entire diseased portion of the bowel could be reached by the fluid. Unfortunately, many physicians and nurses cannot successfully carry out high colonic irrigation, because they are not familiar with the technique of introducing the tube. Certainly the difficulties offered to its passage by the sphincter muscle, rectal valves, O'Beirne's sphincter, and angulation of the bowel near the

*Read before the American Proctologic Society at Atlantic City, N. J., June 8, 1909.

rectal sigmoidal juncture are very great, and require considerable ingenuity to overcome them. In all cases where diarrhea cannot be cured by irrigation through the anus, reinforced by dieting and rest, *surgical intervention* should be resorted to at the earliest opportunity. Fortunately for this class of sufferers, the methods indicated are usually effective, can be quickly performed, and are devoid of danger. The following procedures have been resorted to with more or less success in the treatment of simple and other ulcerative colitis inducing chronic diarrhea: (1) Resection, (2) intestinal exclusion, (3) colostomy, (4) appendicostomy, and (5) Gant's cecostomy with irrigation of the small intestine.

Resection of all or a part of the colon is occasionally justifiable in the treatment of colitis, and is indicated when the functionating power of the intestine is irretrievably lost as the result of exhaustion, extensive ulceration, cicatrices, strictures, multiple polyps, or adhesions.

I have elsewhere* reported a case of chronic diarrhea of years' standing, caused by colitis and multiple strictures, which was cured by excising the rectum, sigmoid flexure, and the descending and right half of the transverse colon. On numerous occasions, when making artificial and excising tumors, I have removed from six to twenty inches of the colon or more without apparent harm.

From my experience with these and other operations of a similar nature, I would not hesitate to remove the entire colon down to the rectum in deplorable cases of ulcerative colitis, because colostomy, appendicostomy, cecostomy, and other procedures do not offer to the patient any hope for permanent relief, while complete excision of the diseased bowel does, and, further, because the operation is not either difficult or dangerous.

Intestinal exclusion is a desirable procedure to employ in ulcerative lesions of the colon where the large bowel is utterly useless or needs rest, when resection or one of the milder procedures to be described are contraindicated. I usually divide the ileum three inches above the cecum, close both ends by a purse-string suture and then unite the proximal end of the ileum to the lower part of the sigmoid flexure (ileosigmoidectomy). Following the operation, the stools are fairly frequent and fluid, but gradually become fewer and more solid until after a few weeks, when they become normal in number and consistency.

Colostomy has been successfully employed many times in the treatment of chronic diarrhea due to intestinal ulceration, but this procedure has not, nor will it ever, become popular, owing to the difficulty encountered in making a satisfactory artificial anus, and, further, because of the danger which accompanies the operation for restoring the continuity of the intestine after the colotis has been cured. A colostomy may be made at any point along the large bowel, but, by preference, the opening should be established well above the disease, otherwise irrigation will be incomplete, the ulcers will not heal, and the diarrhea will continue.

In making an artificial anus in this class of cases, it is not necessary to make a perfect spur, as is done when the operation is performed for the relief of cancer or other pathological conditions causing obstruction, because the bowel can be made to heal by frequent flushings, in spite of the fact that the feces continue to occasionally pass over the ulcerated bowel. I mention this because it is very much easier to close a small opening in the intestine made for irrigating purposes than it is to make an end-to-end or lateral anastomosis and close an effective artificial anus.

The technique of colostomy has been greatly improved, and patients operated upon after the method suggested by me some time ago have a much better control over the artificial opening than was formerly the case, an advantage greatly appreciated by the patient where the opening is to be permanent. In 1892 Gibson suggested a novel way of performing right inguinal colostomy, which has been employed with some success in the treatment of diarrhea. This procedure is looked upon favorably, because it permits a thorough bowel irrigation and, in a measure, prevents the involuntary escape of feces. The point of vantage in this operation is found in the valve-like arrangement formed by three layers of Lambert sutures placed in the cecum, above and below the opening, which serve to invert the bowel about the catheter.

On one or two occasions I have observed feces and gas escape at the sides of the catheter when the bowel was not infolded. This has led me to modify Gibson's operation by forming a circular cone-shaped valve, which is done by introducing three or four serosmuscular purse-string sutures around the incision, which, when tied, invert the bowel equally on all sides about the catheter.

Appendicostomy is at present the most popular surgical procedure practised for the relief and cure of chronic diarrhea. I have elsewhere (*Boston Medical and Surgical Journal*, September 6, 1906) reported eight cases of chronic diarrhea of different types, treated by appendicostomy and through-and-through irrigation. Since then I have handled in the same manner thirty other individuals suffering from ulcerative colitis.

One of my earlier patients died as a result of extensive sloughing of the cecum in the neighborhood of the appendix. In the remaining thirty-seven patients the number of daily stools rapidly diminished immediately following the inauguration of through-and-through irrigation, and their general appearance improved correspondingly. At the end of a week or ten days, with two exceptions, they did not have more than two or three movements daily and had gained considerably in weight; at the end of from four to twelve weeks they had fully recovered from their diarrhea and the manifestations arising from the autointoxication. In the two patients who did not do well I was unable to reduce the evacuations below three or four in twenty-four hours, and these patients would occasionally, after experiencing abdominal discomfort, discharge a number of softer fluid movements and gas. A careful study of these subjects and their stools convinced me that they suffered both from catarrh of the small intestine and ulcerative colitis.

The appendical outlet was kept open in the different cases from five weeks to one year, and in the entire series of cases diarrhea did not return after the opening was closed, with but two exceptions. In both, the irrigation had been discontinued within two months of the time of operation. From this experience I have concluded that it is inadvisable to stop irritation or to remove the appendix sooner than six months, or longer, following the operation. Patients do not insist on early closure, as a rule, because the opening is small and they are rarely bothered with the involuntary escape of gas and

*See Intestinal Exclusion, Gant's Constipation and Intestinal Obstruction, 1909.

feces. In some instances the appendical opening remained free, but in others it was necessary to insert a small catheter to keep ti from becoming occluded.

After a cure had been effected, in a few cases the appendical opening closed spontaneously; in others the aperture was sealed by destroying the mucosa with chemicals, an electrical or a Paquelin cautery, and in the remainder, under local anesthesia, the appendix was freed, ligated, and excised without entering the free peritoneal cavity and the wound closed with plain catgut.

I have previously called attention to the good points of appendicostomy, but now I wish to point out some of its disadvantages. When the appendix is small, short, strictured, or firmly bound down by adhesions, it is useless for irrigating purposes; it occasionally has a tendency to slip into the abdomen during post-operative vomiting and

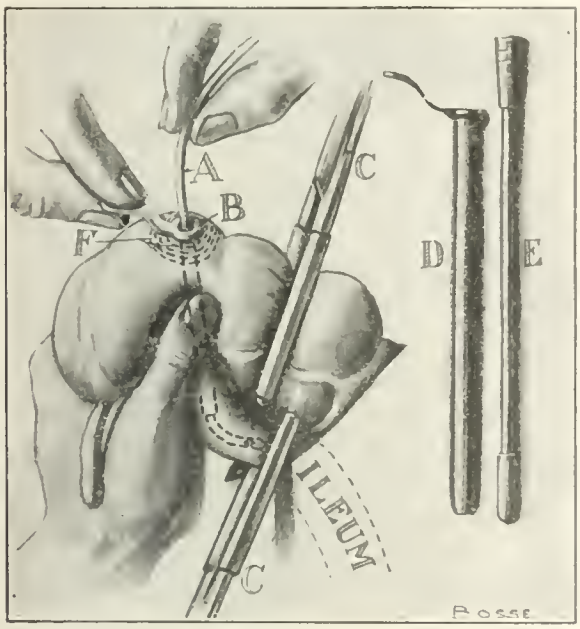

Fig. 1.

early attempts at irrigation; it has been known to become necrotic, and, in one case of my own, death followed from sloughing of the cecum, at the appendical attachment; the appendical opening sometimes requires considerable attention to prevent it from closing, and occasionally valuable time is lost in searching for and freeing the appendix from neighboring structures; finally, it is not a suitable operation to employ when there is both an enteritis and ulcerative colitis, which play their respective parts in causing diarrhea, because this procedure permits only of colonic irrigation.

Cecostomy.—I have employed this method fourteen times in the treatment of diarrhea. In six cases, the procedure of Gibson, which has already been described, was followed, and in the remainder Gant's cecostomy was employed. My cecostomy may be resorted to with success in all cases of cronic diarrhea which are suitable for appendicostomy and those which are not, because of the diseased or deformed condition of the appendix, and also in cases where both the small and large intestine are diseased. Formerly I was prejudiced in favor of appendicostomy, but a larger experience has convinced me that cecostomy, combined with small intestinal irrigation, has a much wider field of usefulness in this and other cases than appendicostomy, and that it should supersede irrigation through the appendix in many instances. Both cecostomy and appendicostomy are desirable procedures, because they are effective, are not dangerous, can be performed quickly, and leave few, if any, undesirable sequalæ. Personally, I have no more hesitancy in advising these operations for the relief of chronic diarrhea than appendicostomy for appendicitis.

I will now describe what I believe to be a new and effective way of irrigating both the small and large intestine through the same opening in the cecum—an operation which, for want of a better name, I have designated "cecostomy with an arrangement for irrigating both the small and large intestine." (Gant's cecostomy.)

The following briefly-described steps in the technique of this operation can be readily grasped by a glance at the accompanying illustrations:

1. Through a two-inch intermuscular incision made directly over the cecum, it and the lowermost part of the ileum are withdrawn and the edges of the wound covered with sterile gauze handkerchiefs.

2. The cecum is scarified and clamped with rubber-covered forceps to prevent soiling of the wound when the bowel is opened. (Fig 1 C.)

3. Four linen or silk seromuscular purse-string sutures are inserted in the anterior wall of the cecum at or outside the longitudinal band directly opposite the ileocecal valve (Fig. 1 F), when the bowel is quickly opened inside suture line by using the knife for the outer coats and the scissors for the mucosa.

4. The bowel is grasped at the juncture of the large and small intestine and held in such a way that the ileocecal valve rests between the thumb and fingers of the left hand (Fig. 1). A Gant catheter guide (Fig. 1, D and E) is then introduced through the incision and carried directly across the cecum, and then suddenly guided through the ileocecal valve into the small intestine by the aid of the thumb and fingers, placed there for this purpose. (Fig 1 B.)

5. The guide is then held by an assistant while the obturator is removed and a catheter, No. 12, is introduced into the small bowel. (Fig. 1 A.) The guide is then removed and the catherer is held by an assistant until it has been anchored to the cecum by a catgut silt suture to prevent its slipping out.

6. A short piece of catheter three inches long is then introduced into the cecum, beside the one which enters the small bowel, for an inch or more (Fig. 2), when both catheters are fastened together by a narrow band of adhesive plaster placed around them, on a level with the skin. (Fig. 2 B.)

7. The clamp is now removed from the cecum and the purse-string sutures (Fig. 2 F) are tied; this inverts the edges of the bowel about the tubes, each stitch in its turn causing a still further circular infolding of the bowel, all together forming a cone-shaped valvular projection all around the catheters, which effectively prevents the escape of the feces.

8. The cecum is scarified and anchored to the abdominal wall by through and through suspension sutures or by chromicized catgut stitches which include the peritoneum and fascia. The wound in the abdomen is closed by the layer method, after which the catheters are stitched to the skin or preferably retained in place by a narrow strip of adhesive plaster between them and attached to the skin. (Fig. 2 A.)

9. Ordinary five-cent cravat clamps (Fig. 2) are snapped over the ends of the catheters to prevent leakage, after which the operation is completed by

applying the ordinary dry dressings, which are held in place by adhesive strips.

Remarks.—One catheter should project further than the other, or they should be identified in some other way, in order that the interne or the nurse may know which is in the large and which is in the small intestine when the time for irrigation arrives. In order to avoid the danger of infecting the wound, irrigation is not begun until the fifth day, unless there is some special reason for it.

In order to avoid irritation to the cecum and skin, it is advisable to occasionally change the catheters. This is done by cuting the adhesive strips holding them together and withdrawing the one projecting into the colon. Gant's catheter guide is then passed over the other and into the small intestine, where it

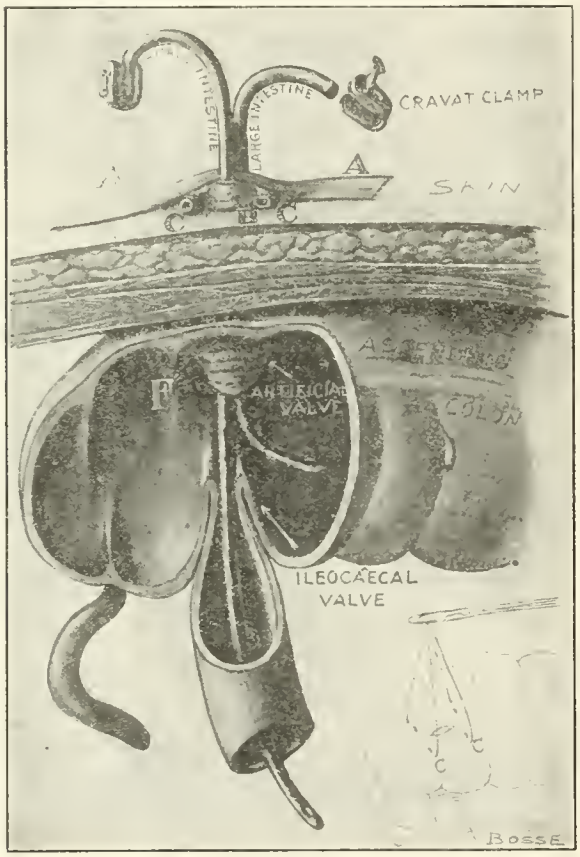

Fig. 2

is held until the old catheter has been removed and a new one inserted, when it is withdrawn. A second piece of catheter is then inserted into the cecum, and then both are prevented from slipping out by two adhesive strips placed around and between them.

Before deciding upon the above-described technic, I attempted irrigation of the small intestine by passing a silver catheter through the opening in the cecum and then the ileocecal valve each time the small bowel was irritated, to avoid the use of two catheters, but this practice was abandoned as impractical because of the difficulty encountered in locating and passing the valve, and, further, because the patient could not carry out this form of irrigation while at home.

I have often been asked if peristalsis had ever forced the soft-rubber catheter out of the ileum and into the large bowel, and wish to state that except in one instance I had no reason to suspect that this has occurred, and that in one case referred to the end of the catheter projected only two inches into the small bowel instead of several, as it should, which makes the accident unlikely. I feel confident that the catheter remained in position in the other cases, because (a) water injected through the pipe in the large intestine was evacuated much quicker than through the one in the small bowel; (b) when a minute quantity of a ten per cent. solution of methylene blue was injected through the colonic tube it manifested itself in the urine more quickly and pronounced than when introduced through the catheter in the small bowel, and (c) the catheter guide could be carried over the tube in the small intestine and it could be removed and replaced with a new one at will, and, further (d), fluid feces could be withdrawn more quickly and frequently through the pipe in the small bowel than through the colonic catheter. To those who fear expulsion of the catheter from the ileum, I advise the use of a silk, silver, glass or other stiff catheter. With such an instrument, the patient can irrigate himself while at home, and when he comes to the office after the colonic catheter has been removed, a double flow pipe can be guided over the tube in the small intestine and it can be thoroughly washed out by the attendant. Under such circumstances, the return flow can be made to discharge into the cecum through an eye in the irrigator or outside through its end.

After the diarrhea has been cured, and when spontaneous healing does not follow the withdrawal of the catheters, the opening may be closed by cauterization, or with sutures under local anesthesia and without the necessity of entering the peritoneal cavity.

Cecostomy with provision for small intestinal irrigation is also useful in the treatment of conditions other than diarrhea. It may be employed to advantage in the treatment of ordinary and pernicious anemias, autointoxication, ptomaine poisoning, diarrheas of children, or for intestinal feeding during the treatment of disease or following operations on the mouth, throat, esophagus or stomach, where rest of these organs is indicated. It can also be used for studying and treating the different parasitic and intestinal diseases, to note the amount and character of the intestinal juices and discharges, the nature of the feces, the direct action of the salines and other cathartics injected into the bowel, the results of hot and cold enteroclysis upon the blood pressure, and many other interesting problems too numerous to discuss in this paper.

There is always a marked improvement in the conditions of persons suffering from chronic diarrhea immediately following effective irrigation through the appendix, the cecum, or an artificial anus, irrespective of the type of colitis causing the trouble, but it requires a longer time to overcome a tubercular than other ulcerated lesions of the bowel. The diarrhea rapidly improves, irrespective of the nature of the solution used. Apparently much of the benefit derived from irrigation is due to the mechanical effect of the fluid in cleansing the ulcers and freeing the mucosa of toxins, irrigating discharges, and debris. Following the operation, the colon should be irrigated twice daily, but later on, in proportion as the ulcers heal and the diarrhea improves, the treatments should be diminished to once daily or two or three times weekly, according to indications. I have obtained good results following daily washing of the bowel with hot and ice water and solutions containing boric acid, common salt, quinine, ichthyol, formaldehyde, colorless hydrastis, krameria and soda, silver nitrates, and other agents too numerous to mention.

When ulceration is slight or moderate in degree, weak solutions do well, but when it is extensive, as indicated by very frequent evacuations containing considerable pus and blood, they should be used stronger until there is evidence of improvement. When there is considerable bleeding, I begin lavage with a solution of silver nitrate, 30 grains to the quart, and gradually decrease the amount of silver as healing takes place.

The stools of persons suffering from chronic diarrhea are often exceedingly offensive. In such cases, an occasional irrigation with a one or two per cent. solution of ichthyol will serve both to deodorize the movements and to heal the ulcers.

In conclusion, I wish to say that my large experience with the surgical treatment of chronic diarrhea has been so very satisfactory that I have no hesitancy in recommending this method above all others in the treatment of this common and distressing ailment.

43 West Fifty-Second Street.

A NOTE ON THE VILLAGE TREATMENT OF NERVOUS INVALIDS.

By L. PIERCE CLARK, M.D.

NEW YORK.

Recent psychiatric study of many functional nervous disorders, such as hysteria, neurasthenia, and the like, has brought about a more comprehensive treatment of these diseases. While a strictly psychogenic cause of these disorders is far from proven, there can be no doubt the mental factors play no small rôle in the fixation and permanency of them. A larger view of the mental and physical causes of these neuropsychoses explains the frequency of relapse. It is no longer sufficient to correct a supposed autointoxication or some physical defect and expect the patient to remain well. Recent studies show that many of these diseases have an inherent defect in the personality, a predisposition which renders a breakdown possible with but little exciting cause. In a detailed search for the psychogenic factors in the development of the malignant psychoses of adolescence the all-embracing terms "hereditary predisposition," "neurotic temperament," and the like, are assuming a more definite and precise meaning. These general terms are being disentangled into their component mental characteristics and habits of thinking, and the reactive effects which such habits have on the physique. In this manner a better knowledge of temperaments, personalities, and the like mental characteristics advances our practical therapeutics for these borderland psychoses.

To overcome these personality defects environmental and social treatment is necessary. The patient must live under a thoroughly detailed plan of daily routine. He should have a community life not too dissimilar to his former life, which should be sufficiently simple that the process of training may be under full control yet stimulative. Many modern sanatoria have done excellent work along these lines. *Occupation* cures of to-day are replacing the *rest* cures of yesterday. The teacher in arts and crafts, the trainer and companion-nurse are superseding the bed-rest nurse. Most observers will admit that sanatoria are limited in treating these borderland psychoses. In such institutions too many mental invalids are thrown together and a diversified family and community life is not possible. The environment is too artificial and cramped to train the patient to the full measure of normal daily habits.

In endeavoring to solve the problem I have made use of the community or village treatment of these nervous invalids. We have in easy access to New York City many beautiful villages just suited to this purpose. The colonization of the insane and epileptic has had this principle in view. The working idea is still better shown in the excellent system of boarding-out the insane in Scotland and other countries; in the latter place the village and home life for social and environmental therapeusis is excellently shown. If the principle works to such advantage for the insane and epileptic, how much greater good should we not obtain for the borderland phychoses and neurasthenias. The sane and peaceful atmosphere of the village life with its good influences must exert a healthful correctional aid for character reconstruction in disordered personalities.

Life in the village of two or three hundred inhabitants gives us a sufficiently varied yet simple social environment to gain poise and healthy initiative for our patients. Colonies for the neurasthenic poor in Germany, Switzerland, and other countries are steps in the same direction, although they must fail in keeping many diseased personalities from too close contact with each other. A normal association of healthy individuals should be thrown about each case.

It has seemed to me, therefore, a wise plan to place a relatively small number of these nervous invalids in each community; not more than one patient and his trainer-companion should be located in one family. Most of these farm homes have gardens and the home accesories of farms—live stock, the care and training of which furnishes interesting and profitable employment. I usually select the farm cottages on the margin of the village, as they are quieter and more secluded. Here the patient can carry out a definite plan of daily work, exercise, and study. Each village can be made to support an arts and crafts shop, and an amusement-gymnasium for physical culture. This scheme requires no financial outlay. It does not commit any one to a great expense, as that which would be required were the whole village and its inhabitants interested in the maintenance of a spa or a large sanatorium town. The idea, if it continues successful, might form the basis of a philanthropic project for the neurasthenic poor, with a missionary order of nurse-trainers to carry on the work.

It is gratifying to note the rapidity with which the transplanted city patients adapt themselves to this village treatment. Morbid ideas and fears are easily uprooted and natural and normal life replaces them. The patient's life is as thoroughly detailed as in the rest cure at first. After a little the patient is given a partly "elective course" of treatment for certain hours of the day. Finally, the patient keeps his own records, reports to the physician direct, and at last he becomes thoroughly autonomous and learns to manage his own affairs, as in health. The somewhat formal and institutionalized homes of the cottage colonies of popular sanatoria are absent here; the plain Anglo-Saxon family life is wholesomely substituted. The family life in the several homes differs in small homely ways. The social note in certain families is thus used as so many special psychotherapeutic remedies.

The informal calls of the specialists give a closer insight into his patient's life which parallels the

position of the one-time village doctor. In not a few instances the violent psychoanalysis of the ultra-modern school may be dispensed with, and the natural confessional of a Dr. Lavender obtains instead. No doubt the result obtained in this manner is as beneficial to the physician as to the patient.

The easy-going, non-stratified village society makes for a diversification of individual influences. Habits of industry, thrift, and self-denial are daily standards in village life. A strict individual responsibility is demanded of all alike. The primitive and rural character of village livelihood makes for a diversified occupation not obtainable elsewhere. This plan of mine works no disadvantage to the permanent inhabitants. Aside from giving an income from the guests, it affords an excellent opportunity for sociologic and practical humanitarian endeavor right at home. Social settlement work and a practical missionary field are provided close at hand.

The type of cases suitable for this village treatment practically includes all the functional neuroses and borderland psychoses. It furnishes excellent opportunity for mental and physical training of individuals suffering from dementia precox and the maniac depressive psychoses in their remission and accessible periods. In brief, one may say that the plan is applicable to all nervous cases exhibiting disorders of personality, constitutional defect, or where mental or moral delinquency obtains.

84 East Fifty-sixth Street.

THE LIQUOR PROBLEM: SOME SUGGESTIONS FOR ITS SOLUTION.*

By CHARLES A. ROSENWASSER, M.D.,

NEWARK, NEW JERSEY.

ATTENDING PHYSICIAN TO THE PRESBYTERIAN DISPENSARY; MEMBER OF ADJUNCT STAFF OF ST. JAMES' HOSPITAL; VICE-PRESIDENT OF THE DEPENDENCY AND CRIME COMMISSION OF THE STATE OF NEW JERSEY.

It seems to me that the time has arrived when physicians who have given thought to all phases of the alcohol question should frankly and fearlessly discuss the practical side of the question, namely, the solution of the liquor problem insofar as it applies to the manufacture and sale of alcoholic beverages. The subject is certainly one upon which men who are earnest, honest, and sane may and do differ. I hope, therefore, for earnest discussion of these few remarks which are based upon personal investigation, conducted solely for the purpose of securing light. I would remind you at the outset that I am discussing the question mainly as it affects the State of New Jersey, though I believe that my conclusions will apply with equal force to other states having a similar cosmopolitan population. My time being limited, I will merely discuss the most important features of the subject.

The evils arising from the use of alcohol are too well known to require discussion. Were there no evils following the use of alcohol there would, of course, be no such thing as a liquor problem any more than there is now a soda water problem. This history of the liquor problem is the history of the world. There always was a liquor problem, and there always will be. For ages wise men have been preaching the doctrine of temperance and of total abstinence. The evil effects of alcohol upon the individual and society are well known to every enlightened person, and yet the number of total abstainers—real, true, total abstainers from alcohol—are but a handful to the tribe of those who prefer to slumber in its bosom. Hence the problem before us is, how can the liquor traffic be conducted with the least amount of injury to the individual and to society?

To me it is clear that many of the difficulties which arise from the use of alcoholic beverages are due to two great faults: (1) impure products, and (2) to our system of handling these products. Whether or not alcohol used in moderation is harmful is a question upon which authorities differ. One great class of skilled scientific observers contends that alcohol is always and under all circumstances harmful to the system; another group of equally skilled observers declares emphatically that alcohol used in moderation and under proper conditions is not injurious, and may indeed be of benefit. Everyone agrees, however, that impure and improperly prepared alcoholic beverages are decidedly injurious, and the excessive use of alcohol in any form has no defenders.

As for impurities, it would be of interest to learn how closely the manufacture of beer to-day corresponds with that of, say, fifteen years ago. The statement is made that the demand for beer is so great that the brewers are compelled to supply the consumer with a product which has not been properly aged or lagered, and that it is necessary to add certain preservatives in order to overcome this defect. That artificial bitters are added is also charged. If these statements are correct, we see a cause for much of the physical deterioration following the use of beer. Dr. Wiley tells us that good whiskey is at the present time almost unobtainable at any price. It is also said that the fancy liqueurs are almost all adulterated, and that the entire world does not grow enough grape to supply anything like the quantity of wine which is consumed. It is apparent, therefore, that much of the wine is made in chemical laboratories. We are led to believe that there is much truth in these assertions, as moderate drinkers tell us that they cannot stand the alcoholic beverages of to-day as well as they could those of a few years ago, and the topers complain that it is impossible to get "good stuff."

The first step in the solution of the liquor problem is, therefore, clear. It is the duty of the State to so strengthen and enforce the pure food laws that those who drink will receive pure goods, and know just what they are drinking. If this be done, the baneful effects of alcohol upon the system will be greatly minimized, and many of the evils attendant upon the liquor traffic would vanish.

As for our system of handling alcoholic products, it seems to me that the greatest evil lies in the American bar. That there are evils following home drinking and other modes of indulgence there is no doubt, but these fade into oblivion before the evils attendant upon the American bar. The bar system is especially vicious because it encourages men to drink when the stomach is empty, to drink hastily, and to drink more than they want. Here lies the great difference between the American and the German liquor problem. The Germans handle the liquor problem much more intelligently than we do, and, therefore, escape many of the evils which we encounter. They have no bars, and the efforts which have been made to introduce the bar system into Germany have met with failure. Germans do not stand up and drink, and each man pays for his own drinks; there is no treating. They usually take

*Read before the American Society for the Study of Alcohol and Other Narcotic Drugs, at Atlantic City, N. J., June 8, 1909.

a bite of bread or other food with their drinks, and they drink very slowly. They drink mainly beer or light wine, and very sparingly of whiskey or the strong liqueurs. Surely we can learn much from our German friends in our efforts to solve the liquor problem.

We should endeavor to do away with the bar system with its attendant evils, and this can gradually be accomplished if we will but take a commonsense view of the matter, and not expect to change in a few months a system which has been engrafted upon society over a long period of years. How can the bar system be done away with? A beginning can be made by permitting the sale of alcoholic beverages on Sunday in restaurants and hotels, but only with meals, and *only in places having no bars.* Some will say, if you do this, you will soon find our saloons turning into restaurants. I admit this to be my object, for we must do away with the bar if we wish to lessen the evils of the liquor traffic. If those persons who will drink will learn never to take alcoholic beverages without partaking of food at the same time, also to drink slowly, and to refrain from treating each other, a great deal will have been accomplished toward lessening the evils associated with the taking of alcohol. But the individual who has, or has had, the drink habit must avoid alcohol in every form, and under all conditions, if he is really desirous of overcoming the habit.

We should encourage the use of mild alcoholic beverages, such as beer and light wine in place of the stronger ones, such as whiskey. This can best be done by permitting the sale of the milder preparations under a much lower license fee than that charged for the sale of the stronger.

The campaign of education must continue with renewed energy in the hope of reducing the demand for alcohol, for alcohol, like every other commodity, obeys the law of demand and supply. Children especially should be taught the effects of alcohol upon the human body, so that they can see for themselves why it is best for them never to touch alcohol. We should lay greater stress upon the physical effects of alcohol than upon the moral effects, for we know that there is nothing so conducive to healthy morals as a healthy body. It will be easier to impress upon a child the wisdom of avoiding alcohol in every form if we make it clear to him that alcoholic beverages weaken the body and thereby reduce the chances of success in the great battle of life.

In theory the liquor problem is easily solved, but not so in practice. My prohibition friends think they can solve this great world problem by a word—Prohibition. I try to keep an open mind upon all subjects, and shall certainly be glad to welcome prohibition to New Jersey if in time it will prove to do for those states which have adopted it that which its friends claim for it. From my studies of its operation I am opposed to prohibition. My opposition is mainly because prohibition encourages the use of the stronger alcoholic beverages in place of the milder ones. Remember, if you please, that the specially injurious ingredient of all alcoholic beverages is the alcohol contained. The more alcohol taken the greater is the injury inflicted. A pint of light wine contains about one and one-half ounces of alcohol. A pint of whiskey contains about ten ounces of alcohol. Prohibition encourages the use of whiskey in place of wine or beer. This is strikingly shown in the report of Internal Revenue Collector Bittman, of Cincinnati, O., for the month of May past, from which we learn that there was in "dry" territory a slump of 15,000 barrels in the production of beer, and an increase of 50,000 gallons in the whiskey output!

In justification of prohibition, our Southern friends refer to the women of the South being exposed to the dangers of "booze-crazed" negroes. Is the "cocaine-crazed" negro any less dangerous, or is he more so? Is not prohibition driving persons of both races to the use of drugs which are far more harmful than is alcohol? If not, how can we account for the tremendous sale in prohibition territory of so-called temperance drinks containing cocaine? Dr. Spratling of Baltimore says that there are in the Alabama Insane Asylum four hundred negroes who have become insane through the use of cocaine.

Local option, as a remedy for the evils of the liquor traffic, is a misuse of the great American principle of majority rule. If the traffic is an evil one for one county, it is just as great an evil for the neighboring county. Local option tends to shift the responsibility for the traffic from one shoulder to the other. We will never solve the problem in that fashion. Local option means local prohibition and local strife.

High license is another remedy which has many supporters. Its friends claim that it will limit the number of saloons and will elevate the tone of the business. That the number of saloons should be limited according to the population is conceded by everyone. This, however, should be fixed by law, irrespective of the license fee. Aside from reducing the number of saloons, high license is of no value and may indeed work harm. It merely tends to wipe out the small saloonkeeper in the poorer sections who is doing a respectable family trade and who can manage to eke out a bare living only because he employs no help, doing all the work himself, or being aided by a member of his family. High license does not put out of business the dishonest saloonkeeper who sells impure goods, and who otherwise robs his customers by giving them short change or counterfeit money, or by overcharging them. The saloonkeeper who is a crook and whose saloon is a den of vice is perfectly well able to pay any license fee, no matter how high it may be.

In recapitulation, I would make the following suggestions in answer to the question, How can the liquor traffic be conducted with the least possible amount of injury to the individual and to society?

1. Teach the people, especially children, the wisdom and importance of leaving alcohol in every form severely alone.

2. Recognizing that, in spite of all teaching, the vast majority of people will drink alcoholic beverages, regulate the traffic by just and sensible laws, and enforce the laws.

3. Insure the purity of alcoholic beverages by strengthening and enforcing the pure food laws.

4. Discourage the bar system by encouraging the establishment of restaurants having no bars.

5. Discourage the use of the stronger alcoholic beverages by encouraging the use of the milder ones, such as beer and light wine, in their place.

6. Try to put a stop to the treating custom.

7. Treat, in properly equipped hospitals, or farm colonies, the victims of the drink habit.

THE AMOUNT OF LUNG INVOLVEMENT AT THE ONSET OF PULMONARY TUBERCULOSIS.*

By HARRY LEE BARNES, M.D.,
WALLUM LAKE, R. I.
SUPERINTENDENT OF STATE SANATORIUM.

Three years ago I showed that 50 per cent. of patients having pulmonary tuberculosis delayed consulting physicians for over seven months after the onset of symptoms, and that notwithstanding these delays, 46 per cent. of the patients were given an incorrect diagnosis by their medical advisers.[1] These statistics have been recently confirmed by Stoll.[2] If through education of laymen and physicians both these sources of delay in diagnosis could be eliminated, and all patients come under intelligent supervision soon after the onset of symptoms, how many would be suitable for sanatorium treatment? How many would be curable? How many would be sources of contagion to the community? In attempting to answer these questions it will be found that a knowledge of the amount of lung involvement at the onset of pulmonary tuberculosis is of considerable importance and that scant data on this subject are at present available. It is well recognized that persons frequently recover from slight tuberculous lesions in the lungs without ever having symptoms, but such cases cannot be considered in an inquiry of this kind. The statistical material which forms the basis of this article was derived from the records of 860 cases of pulmonary tuberculosis which have been admitted to the Rhode Island State Sanatorium since its opening.

Of the 860 patients only 120 were received within two months of the onset of pulmonary symptoms, and of these 33 were admitted within one month of the onset. In 87 of these 120 cases, records of the examining physicians were obtained, and in all of these the record of presumable duration coincided with ours. Fourteen other cases which did not coincide were excluded. In attempting to determine the exact date of onset it should be appreciated that the majority of patients greatly underestimate the length of duration of the disease. Histories taken by those who do not appreciate this fact, or who lack the time or inclination to put the patient through the most searching cross examination to avoid these errors, are almost valueless for this purpose. No pains have been spared to make these histories accurate in this respect. A considerable number of patients give a history of digestive disturbance, or of feeling tired for some time before the onset of the first pulmonary symptom, but as there must always be doubt as to whether these symptoms result from tuberculosis, and as neither laymen nor physicians can be expected to look for tuberculosis in such cases, it is not practicable to regard anything but the occurrence of symptoms pointing to pulmonary disease as an onset. In the great majority of cases the first symptom noticed is a cough, and yet a cough so frequently results from trivial causes, that if slight and unaccompanied by troublesome symptoms, it is unlikely to bring the patient to his physician within a month. Cases having hemorrhages or positive sputum may be recognized at once, but when, as frequently happens, the signs are very slight and the sputum absent, another month may elapse before the physician is able to make the diagnosis; so that two months may be set as a reasonable maximum time within which the intelligent patient who consults a well-trained physician should receive a positive diagnosis.

Of the one hundred and twenty patients, sixty-seven, or 55.8 per cent., had tubercle bacilli in their sputum on admission, and one additional case, or .8 per cent., had bacilli after admission. Of the fifty-two remaining patients, thirty-four reacted positively to the tuberculin test, and of the remaining eighteen, nine had had hemorrhages from the lungs, two had had pleurisies, two were complicated by glandular tuberculosis, and in the remaining five patients the symptoms and physical signs were held to be sufficient for diagnosis. These one hundred and twenty cases were classified according to the scheme of the National Association for the Study and Prevention of Tuberculosis, with the following result: Incipient, 31 cases, or 25.8 per cent.; moderately advanced, 78 cases, or 65 per cent.; far advanced, 11 cases, or 9.1 per cent.

The term, "moderately advanced," as defined by the National Association, is so broad that it includes many cases as favorable as the incipient cases, and others nearly as unfavorable as the far advanced cases. In order to give a better idea of the prognosis, it may be said that 85, or 70.8 per cent., were considered mild, and 35, or 29.1 per cent., were considered severe in their type. When classified according to Turban the following result was obtained: Class 1, 33 cases, or 27.5 per cent.; class 2, 52 cases, or 43.3 per cent.; class 3, 35 cases, or 29.1 per cent.

In thirty-three cases but one lung was affected, and in the remaining eighty-seven cases both lungs were affected. The number of lobes involved was: One lobe in twenty-five cases, or 20.8 per cent.; two lobes in thirty-six cases, or 30 per cent.; three lobes in twenty-seven cases, or 22.5 per cent.; four lobes in twenty-two cases, or 18.3 per cent., and five lobes in ten cases, or 8.3 per cent.

Dullness was present in 74.1 per cent. of the cases, and its presence was questionable in 10 per cent.; interrupted breathing was present in 18.3 per cent., bronchial breathing in 11.6 per cent., the apex was involved in 83.3 per cent., and cavity signs were present in 7.5 per cent. The first symptom noticed was: Cough in 89 cases, or 74.1 per cent.; hemorrhage in 13 cases, or 10.8 per cent.; pleuritic pain in 9 cases, or 7.5 per cent.; fever in 3 cases, or 2.5 per cent.; some one of the other symptoms in 6 cases, or 5 per cent.

The symptoms present during the first two months were as follows. Forty-eight and three-tenths per cent. of the patients claimed to have had fever previous to admission. After admission, 7.5 per cent. had fever (daily temperature above 100° Fahr.) for one week, 5.8 per cent. for two weeks, 3.3 per cent. for three weeks, and 13.3 per cent. for four weeks or over. The total number who had fever for these periods was 36, or 30 per cent. Eighty-five per cent. of the patients had had cough, 80 per cent. expectoration, 36.6 per cent. hemorrhage, 21.6 per cent. pleuritic pain, 2.5 per cent. pleuritic effusion, 33.3 per cent. dyspnea, and 57.5 per cent. loss of appetite; 85 patients had averaged 9.9 pounds loss of weight; 33 3-10 per cent. of the patients had had chills, 49.1 per cent. night sweats, 32.5 per cent. hoarseness, and 40 per cent. gave a history of marked exposure to infection.

Of the ninety-one patients who have left the

*Read before the National Association for the Prevention of Tuberculosis, May 15, 1909.

institution up to the present time, the condition on discharge was: Apparently cured, 15 cases, or 16.4 per cent.; arrested, 31 cases, or 34 per cent.; improved, 24 cases, or 26.3 per cent.; unimproved, 21 cases, or 23 per cent. Many of these patients have been discharged too short a time to judge fairly of the results of treatment, but of twenty-six patients having severe onsets, who could be traced, twelve, or 46 per cent., died within an average period of nine months after admission, and of the remainder, ten, or 38.4 per cent. are living, and but four, or 15.3 per cent. are well. If it be assumed that the results of treatment in this series of cases is the same as those obtained in other cases, only seventy-five of the one hundred and twenty patients would be economically cured two years after discharge.* In other words, only a little over 60 per cent. of patients having pulmonary tuberculosis can hope to have their working capacity restored even though the disease has been promptly diagnosed and the patients have been treated in sanatoria.

It is conceded that the statistics of a sanatorium having a waiting list, which enables it to exclude the acute febrile cases,would not furnish proper material for this study, but until recently the lack of a waiting list at Wallum Lake has almost invariably prevented the rejection of applicants with febrile onset and of short duration. It may even be feared that the willingness of patients having a severe onset to enter a sanatorium may have swelled the number of severe onsets. As early hemorrhage cases are usually of a mild type (thirty-two of the forty-four cases with hemorrhage previous to admission being favorable cases), it seems likely that the willingness of the mild cases having a hemorrhagic onset to enter the sanatorium has tended to preserve the normal balance. Tuberculosis dispensaries in large cities afford opportunities for the observation of all types of onset which should be made use of to collect data bearing on this subject.

A summary of the condition of one hundred and twenty cases of pulmonary tuberculosis examined within two months of the onset is as follows: (1) According to the classification of the National Association, 25.8 per cent. were incipient, 65 per cent. moderately advanced, and 9.1 per cent. far advanced; (2) following the classification of Turban, class 1 contained 27.5 per cent., class 2 43.3 per cent., and class 3 29.1 per cent. of the cases; (3) one lobe was involved in 20.8 per cent. of the cases, two lobes in 30 per cent., three lobes in 22.5 per cent., four lobes in 18.3 per cent., and five lobes in 8.3 per cent.; signs of disease in both lungs were present in 72.5 per cent. of the cases; (5) open lesions, causing the patients to be immediate sources of contagion, were found in 56.6 per cent. of the cases examined; (6) about 60 per cent. were economically curable, *i. e.* capable of being sufficiently restored to do a full day's work two years after discharge.

REFERENCES.

1. *Journal of the American Medical Association*, Feb. 16, 1907, Vol. XLVIII, pp. 601-605.
2. *Yale Medical Journal*, March, 1909.

*Our records of 377 cases show that of all patients under treatment for a minimum period of three months, 85.7 per cent. of the incipient, 60.4 per cent. of the moderately advanced, and 26.6 per cent. of the far advanced were arrested or apparently cured, and that 85.7 per cent. of such cases were able to do a full day's work two years after discharge.

Twisted Pedicle in Parovarian Cysts.—Giuseppe Fessati says that in 27 per cent. of all parovarian cysts the pedicle becomes twisted. He cites 109 cases recorded in medical literature, and eleven personally observed. The twisting is favored by absence of adhesions, multiparity with consequent relaxation of abdominal walls, pregnancy from the same cause and from the changes in position of the uterus as it grows, etc. The twists may be from one to five in number, and on the number, tightness, and the size, thickness, and length of the pedicle depends the severity of the symptoms. The common symptoms are edema, congestion, diffuse hemorrhage, pain, hematoma, necrosis, and fatty degeneration of the tumor. Ascites is rare, as are crises accompanied by rise of temperature. Diagnosis is difficult during the crisis, but after that is over it may be made by the presence of a movable tumor separate from the ovary, partially fluctuating, and painful on pressure. Extirpation by median laparotomy is indicated, and the prognosis of the operation is good.—*Annali di Ostetricia e Ginecologia.*

Tuberculosis and Pregnancy.—V. Bué says that both mother and child must be considered in the treatment of tuberculosis with pregnancy. Careful out-of-door treatment may allow of the successful ending of pregnancy. The prognosis for the mother is generally bad. After labor there is pretty sure to be a renewal of the bacillary process even when it was stationary. The infant is generally born healthy, but should not be nursed by his mother. Tuberculous laryngitis is especially badly affected by pregnancy, and here artificial abortion is indicated.—*Le Nord Médical.*

Suprarenal Opotherapy in Obstinate Vomiting of Pregnancy.—T. Silvestri, starting from the fact that in Addison's disease incoercible vomiting continues for weeks at times, and from the results of the work of Tosatti with rabbits and guinea pigs in a state of pregnancy, has attempted the treatment of vomiting of pregnancy by suprarenal extract in a very severe case in which all other methods of treatment, hygienic, psychic, and medicamentous, had been tried without avail. Believing that the insufficiency of the suprarenal capsules might play an important part in this condition of autointoxication in pregnancy, he administered to the patient a preparation which contained all the substances contained in the suprarenal capsules, using tabloids of suprarenal capsule. An immediate amelioration of symptoms was noticed, and in two days' time the vomiting had stopped entirely. The patient continued well at the time of writing, taking one tabloid each day. The immediate effect showed that the treatment had reached the cause of the symptoms, which confirms the theory on which it was based.—*La Riforma Medica.*

Endemic Foci of the Febrile Variety of Infective Splenic Anemia of Infants.—Umberto Gabbi distinguishes two varieties of splenic anemia, the afebrile and the form accompanied by high temperature. The latter appears most frequently in male children from ten days to four weeks of age. The symptoms are profound anemia with edema, splenomegaly, and gastrointestinal disturbances. There are no glandular or osseous lesions accompanying it, nor stigmata of hereditary syphilis. This disease often attacks more than one child in a family; in none of the cases observed by the author were there any bone troubles, respiratory, or circulatory symptoms. The infants attacked were not the weak ones of the family; there were no symptoms of rickets or syphilis found in any of the author's cases. The parents were from the class of fishermen, sailors, and laborers. The author gives the histories of three cases in detail. These cases are not found in malarial regions, nor were there malarial parasites found in the blood on examination. They lived along the seacoast. All of them occurred in a short period of time, and more than one member of a family was affected. There seem to be foci from which the cases are all derived by contagion. All these facts seem to show the contagious nature of this form of the disease.—*Il Policlinico.*

Congenital Bronchiectasis.—Z. Capuzzo describes two forms of congenital bronchiectasis, one arising from a non-inflation of portions of the lung, the other arising during fetal life. The last named form may depend on an arrest of development after the third or fourth month of fetal life. The symptoms are cyanosis, dyspnea, and cough arising some weeks or months after birth. Nineteen cases have been published. There seems to be a combination of a passive mechanical action, due to the increase of fluid transuding from the capillaries and an active proliferation of the epithelia that is not truly neoplastic, but hyperplastic. The atelectatic form results from noninflation of a portion of the lung, the inflated portions becoming dilated by negative pressure occurring during inspiration. There is no sign of anthracosis or inflammation. This is extremely rare, only nine cases being reported.—*Rivista di Clinica Pediatrica.*

THE PANCREATIC ACTIVITY.

DURING the past few years numerous methods have been advocated for the estimation of the secretory activity of the pancreas, most of which, though possibly useful in the laboratory, have proved of little value to the practising physician. Metabolism experiments, though of great value in research work, are much too complex and tedious for practical application; the Cammidge test requires a skilled chemist to carry it out; and Adolf Schmidt's nucleus digestion method, while reliable, is of qualitative value only and gives no quantitative indication of the activity of the gland. Recently, however, Wynhausen has been experimenting with a new test for which, in an article in the *Berliner klinische Wochenschrift* for July 26, 1909, he claims the two advantages of simplicity and quantitative accuracy. His method consists in estimating both the diastatic and the proteolytic power of the stools. The carbohydrate-splitting ferments of the digestive tract come from the saliva, the pancreatic secretion, and slightly from the secretion of the intestinal glands. The former is practically destroyed by the acid of the stomach and the latter is small in amount and acts only on the disaccharides, not affecting the polysaccharides, such as starch. Wynhausen's method is an estimation of the starch-splitting power of the feces.

The stool, which must be fluid, either from diarrhea or made so by cathartics, is filtered, and quantities are put into twelve test tubes, as follows: Of undiluted filtrate, 0.25 and 0.1 c.c.; of filtrate diluted ten times, 0.6, 0.4, 0.25, 0.16, and 0.1 c.c.; of filtrate diluted one hundred times, 0.5, 0.25, and 0.1 c.c.; and of filtrate diluted one thousand times, 0.5 and 0.25 c.c. To each tube is added 5.0 c.c. of a one per cent. solution of soluble starch. After twenty-four hours in the thermostat, the tubes are filled with distilled water nearly to the top, and to each is added one drop of a one-tenth normal solution of iodine. If any unchanged starch remains the solution turns blue; if erythrodextrin is present without starch, it becomes red; while if there are the lower digestive products only, no color is produced by the iodine. The author takes the colorless solution as the end reaction of his test, and adopts as a unit of digestion the number of cubic centimeters of starch solution which would be completely digested by 1 c.c. of the undiluted feces. For example, if 0.1 c.c. of the filtrate is required to digest the 5 c.c of starch solution the digestive power of the stool is considered to be of fifty units, while if 0.01 c.c. only is needed, it is of five hundred units.

In examining nearly two hundred patients Wynhauser found that the diastatic power varied as a rule between 500 and 20,000 units. Considering 50 units to be the low limit of the normal he found seven cases falling below this, among them one of obstruction of the pancreatic duct, two of hemorrhagic pancreatitis, and two of advanced cardiac disease, in which he believed that chronic passive congestion reduced the pancreatic secretions. Simultaneously with this diastatic test he ran twelve other tubes with similar dilutions of feces to which he added casein, to estimate the proteolytic power according to the common method of Fuld and Gross. As a rule the diastatic power of the stool and the proteolytic power were about equal, though variations occurred, in some cases one factor, in some the other, being the greater. The simplicity of the technique of this method speaks in its favor, as does the fact that it offers a fairly definite quantitative determination of pancreatic activity. If further investigations prove it to be reliable and accurate it should be a useful addition to the clinical laboratory, and a valuable aid in the diagnosis of some of the obscure abdominal conditions.

THE RETURN TO BREAST FEEDING.

IT is no recent discovery that no milk, however ingeniously "modified," can ever entirely replace in all essentials normal milk from the breasts of a healthy mother. Even before a scientific study of the composition of cow's milk with a view to its adaptation for infants was well undertaken, no less a person than Oliver Wendell Holmes declared that "a pair of substantial mammary glands were worth far more than the most learned dissertation from the shriveled forefinger of the most-learned professor." In a recent issue of *The Journal of the American Medical Association*, Ostheimer of Philadelphia enters what he calls a plea to physicians not to begin artificial feeding without first trying to help the mother maintain her milk supply. Too often at the urgent request of a mother or some member of the family the physician is induced to "dry up" what little milk the breasts were endeavoring to secrete and begin the discouraging task of working with top milk, boiled water, milk sugar, lime water, cereals, etc., prescribed as to the percentage of this or that which might start the baby properly on its fight for life. Too often also the physician has found a less scientific and more practical attendant succeeding him, and working wonders by calling in the right kind of a wet nurse when the marasmic baby seemed to be swiftly and surely sliding away from life. It has been recently shown that women are about as able in these days to nurse their offspring as ever they were, and that in general failure to do so has been the fault of inclination rather than ability. Even though the mother dislikes the task, persuasion, encouragement, good advice, and

perseverance have taught her at least to tolerate it, and have made her heart glad through the splendid health which her offspring, as infant and child, has thus secured. As in many other matters of medical management, preparation and prevention are watchwords to success.

Breast feeding influences favorably not only the stomach but other organs of the child, notably the skin. L. Duncan Bulkley, upon investigating mothers who declared their inability to nurse, frequently found metabolic errors which, when corrected, permitted the function again to be restored. In eczema of babies he treats the mother with arsenic and iron, stops tea and the taking of stout, and also directs the mother to drink eight ounces of milk with one-third hot water upon rising in the morning, and leaves the baby alone. He declares that in many cases the infantile eczema disappears.

Probably it is quite as important to analyze the mother's milk after labor as to examine the urine before labor. At any rate the child must live on milk, and it seems rational that we should know pretty definitely the exact percentages as well as the quantity secreted in twenty-four hours of that important fluid. Hitherto analysis of breast milk has been carried out chiefly by pediatrists, and the general practitioner has contented himself with knowing something of the microscopic qualities of the patient's secretion. It may be that closer attention to this essential would reduce infant mortality and do away with much vexatious figuring of bovine milk prescriptions.

Satinwood Dermatitis.

The various forms of occupation diseases are always matters of considerable interest, and often prove to be decidedly baffling to the physician on whom falls the duty of diagnosis. That this is especially true of conditions affecting the skin has been demonstrated recently by the fiasco in Washington of a worker in a pulp mill, poisoned by "black ash" being imprisoned for nearly a year as a supposed leper. In the number of the *Deutsche medizinische Wochenschrift* for August 12, 1909, Wechselmann of Berlin calls attention to a severe form of trade dermatitis, about which but little seems to have been written. The condition occurs among expert cabinet makers, and is due to poisoning from satinwood. A peculiar feature of the attacks is that the first does not occur until from ten days to two weeks after the original exposure to the satinwood dust. During this preliminary period there may be a slight sensitiveness of the skin and itching, but nothing more. At the end of the ten days, however, an acute erysipeloid inflammation appears, persists for several weeks, and is so intense that the patient is obliged to give up his work. On return to work, even if not directly handling the satinwood, and exposed only casually to the dust of it in the shop, there is a recurrence in a few hours, an experience which is repeated as often as the patient renews the exposure. This characteristic suggests that the idiosyncrasy to the poisoning is probably of the nature of a true anaphylaxis, whereas some workmen after the original period of itching, develop an immunity to the poison and have no further symptoms; in others the initial infection produces an anaphylactic hypersensitiveness which shows itself by a violent reaction to even the slightest grade of poisoning. In this the condition is probably very similar to the susceptibility of certain persons who, having considered themselves immune to the dermatitis of rhus toxicodendron, after once becoming infected, ever after are hypersensitive to the plant. In the case of the satinwood the poisonous symptoms are due to an alkaloid which can be extracted from the wood, crystallizes from ethyl alcohol, melts at 182° to 183° C. and combines with hydrochloric acid to form a salt with the formula $C_{22}H_{25}O_7NHCl$. A faint trace of this alkaloid when placed on the skin of a susceptible individual will produce the characteristic dermatitis.

The Action of Lecithin in Anesthesia.

Few subjects in medicine have caused more discussion among physiologists than the theories of the cause of anesthesia and the physiological action of those drugs which cause loss of consciousness. The theory of Meyer and Overton is possibly as widely accepted as any. This holds that the action of the anesthetic is upon the lipoid of the brain cells, that it forms a chemical combination with it, and thereby destroys temporarily the functioning power of the cell. Reicher further found that during anesthesia the amount of lipoid, and especially of lecithin, in the blood was greatly increased, and he believed that the action of the anesthetic was to dissolve out the lecithin from the brain. Taking these two theories as his basis, Nerking of Düsseldorf has recently investigated the effect of the administration of lecithin on the action of various local and general anesthetics, and has reported his results in the *Münchener medizinische Wochenschrift* for July 20, 1907. Working with considerable numbers of rats and rabbits and a few dogs, he injected lecithin in solutions of one per cent. intravenously and ten per cent. subcutaneously or intraperitoneally, before, during, and after the administration of ether, chloroform, morphine, morphine and scopolamine, and several of the newer substances used as local anesthetics. In each case a control animal of the same weight was used and given the same dose of the anesthetic. The results were strikingly uniform. When the lecithin was given before or with the anesthetic, much larger doses were required to produce narcosis than in the control animals which had not received the lecithin. When it was given following complete narcosis, in every case the animal became conscious many minutes before the control animal, and the after-symptoms were less severe and more transient. The action of the lecithin seemed to be equally prompt and definite whether the anesthetic were administered by inhalation, subcutaneously, or intravenously. The physiology of its action is believed to be that the injected lecithin either attracts the anesthetic which is bound to the brain lecithin, if Meyer and Overton's theory of anesthesia is correct, and so removes the poison from the brain; or else, if Reicher's theory is the true one, that it supplies new lecithin in the place of that which has been dissolved out by the anesthetic. These results are purely experimental and have not yet been applied outside of the laboratory. As lecithin is a harmless substance, it is probable that the practical use of it on man will soon be made, and if the experiment is successful it may give a valuable means of shortening anesthesia and relieving its disagreeable after effects.

The Blood in Rhachitis.

Some observers have thought a relationship existed between the pseudoleukemic anemia of infants and rhachitis, but no agreement has yet been reached on this point. Not a great deal of attention has been given to the study of the blood in rhachitis, and the results of the recorded observations have not been altogether concordant. For the purpose of harmonizing these apparent discrepancies Leonard Findlay undertook a clinical study of the blood in cases of uncomplicated rhachitis, and, according to his report published in the *Lancet*, found among other things that anemia is by no means the rule; on the contrary, the hemoglobin percentage and the number of erythrocytes were notably high in the majority of cases. He attributes these conditions to a reaction on the part of the economy in an endeavor to compensate for the deficient amount of oxygen and the defective respiration on which he believes the disease to depend. There was considerable variation in the size of the red blood corpuscles, but only occasionally poikilocytosis. Polychromatophilia was uncommon, and nucleated red blood corpuscles were rare. The leucocytes varied considerably in number, leucocytosis being present in a majority, although as a rule in but slight degree, leucopenia in a smaller number, and no numerical change in a few. A more characteristic feature was the high proportion of mononuclear cells, with metachromatic granulation. Enlargement of the spleen was rare. The facts noted clinically were in close agreement with the findings of experimental observations.

News of the Week.

The National Association for the Study and Prevention of Tuberculosis has issued a bulletin urging physicians not to send advanced and indigent cases of tuberculosis to the Southwest. It says that 7,180 hopeless invalids migrate annually to these States, fifty per cent. of whom are so far advanced in the disease that they cannot be cured in any climate, and sixty per cent. are so poor that they are unable to provide the ordinary necessities of life. It costs at least $50 per month for the support of a patient in this region, and to send out those with less than that insures their either dying of privation or starvation, or becoming objects of public charity in a country where the resources of the charitable institutions are already strained to the utmost.

Typhoid Fever in New York City.—The hospitals on the upper East Side of New York City are contending with an unusually large number of cases of typhoid fever. Most of the cases have come from the district between Fifty-ninth and Seventy-eighth streets and First and Second avenues, which is a congested tenement section. The source of the contagion has not been determined. At the beginning of this week 202 cases were reported as being in ten of the hospitals as follows: Bellevue, 32; Beth Israel, 20; Flower, 18; Fordham, 20; Gouverneur, 5; Harlem, 10; Lebanon, 8; New York, 20; Presbyterian, 38; Roosevelt, 31.

Annual Bridewell Report on Crime.—The thirty-seventh annual report of the House of Correction, Chicago, was recently published, and in it there is a comment on relation of disease to crime and a recommendation for a city hospital for alcohol and drug addictees. During 1908 the House Physician (Dr. C. E. Sceleth) wrote that "12,427 inmates were received; 576 cases of delirium tremens were treated in the hospital; 1,018 alcoholics or 'drunks' were treated in the cell houses; fifty-one cases of drug habitues who had been 'fiends' for years and were using from fifteen to sixty grains of morphine a day were given treatment and relieved of the habit in two weeks; 342 persons were received who had been using cocaine, smoking opium, and using nostrums containing false stimulants and sedatives, who only needed to be deprived of the drug to recover." After mentioning that Chicago has no hospital for such cases and that they are refused by the county hospital, the physician urged that the city build a hospital on the grounds and accept remuneration from those patients to help pay for the charity cases.

The Queen Alexandra Sanatorium for tuberculosis patients will be opened early in the autumn at Davos, Switzerland. This institution, though founded by English charity and considered as national in character, is to be open to all members of the English speaking races, whether British subjects or citizens of the United States. The sanatorium will accommodate fifty-four patients at first in private rooms. It will, however, be greatly enlarged if the present plans are carried out. The requirements for admission are that the patients belong to an English speaking nationality, be medically suitable, and be able to show evidence of inability to afford treatment in private sanatoria and hotels.

County Tuberculosis Hospitals.—Following the passing of the new law in New York State, permitting counties to establish hospitals for tuberculosis, active steps are being taken in the counties of Onondaga, Oswego, Cayuga, and Schenectady to found such institutions. Oneida County has such an institution on the grounds of the almshouse at Rome. The labor unions of Rome have raised money for an extra pavilion for those who will not go to the almshouse. Ontario County has already made an appropriation for such a hospital. Ex-Governor Odell has endowed a hospital for Orange County at Newburgh. Elmira received a similar gift from Mr. and Mrs. Rapelyea. Poughkeepsie has a model day and night camp. Buffalo, Rochester, and Brooklyn have made special provision, and many other localities are strongly agitating the question.

New Dispensary in Milwaukee.—The Catholic Colored mission has opened a medical dispensary in its headquarters, 530 State street, Milwaukee, with Dr. W. V. Nelson acting as physician in charge.

The Missouri State Board of Health has opened official headquarters at Jefferson City, Mo., with offices in the old Supreme Court Building. Dr. Frank B. Hiller of Kahoka, secretary of the board, will be in charge. Under an act of the last Legislature the State Board of Health is required to open an office in Jefferson City and gather vital and mortuary statistics. The board has taken steps to put the vital statistics law into operation. A committee will cut the State up into convenient districts and arrange for the appointment of registrars in each district so created. This will mean the appointment of not fewer than 10,000 men to collect and make a report in their districts each month of all births and deaths and forward their reports to the State registrar at Jefferson City. Some of

these will be physicians, although anybody is eligible. Under the law the registrars will collect a fee of 25 cents for each birth or death reported. The Districting Committee will report to the board at a meeting to be held at Kansas City on September 20. The appointment of the registrars will be made by December 1, and the law made operative by January 1, 1910. The statistics will be collected and kept in conformity with the regulations prescribed by the United States Census Bureau.

New Polyclinic Hospital.—The trustees of the New York Polyclinic Hospital have purchased a plot of ten lots on the north side of Fiftieth street and the south side of Fifty-first street between Eighth and Ninth avenues as a site for a hospital that will be among the largest in the city. The property secured for the building has a frontage of 153.4 feet on Fiftieth street and 40 feet on Fifty-first street. The hospital will be twelve stories high and will cost about $1,000,000. It will be the tallest hospital in the city and will be modern in every respect. The new building will be used as the headquarters of the institute and the old building on Thirty-fourth street just east of Third avenue will be continued as an east side branch.

Appointments.—Dr. Henry M. Bascom, Ottawa, Ill., has been appointed Chief Surgeon of the Illinois Traction System and of the Hospital Association of that system; Dr. John M. Phifer, Stewardson, Ill., has been appointed Assistant Surgeon of the Atcheson, Topeka, and Santa Fé Hospital, Topeka, Kan. Dr. H. Gideon Wells has been appointed Assistant Professor of Pathology of the University of Chicago, and Dr. A. J. Carlson has been appointed Associate Professor of Physiology in the same institution. Dr. Julius Wenglesky, chief of the medical staff of the Illinois Eastern Hospital for the Insane, has been appointed acting superintendent of the institution in place of Dr. J. L. Greene, who has resigned to take the place of alienist on the State Board of Control. Dr. Allen J. Smith has been elected dean of the Medical Department of the University of Pennsylvania in the place of Dr. Charles H. Frazier who has resigned. Dr. Joseph Walsh has been appointed consulting physician in the department of tuberculosis at the Philadelphia General Hospital. Dr. John B. Stetson has been appointed third assistant bacteriologist to the Philadelphia Bureau of Health, in succession to Dr. Mortimer Herzberg, who has resigned to accept the chair of Pathology and Bacteriology in the University of South Dakota, and the directorship of the State Hygiene Laboratory.

The International Dental Congress, which was held in Berlin during the week ending August 27, seems to have been nearly wrecked on the shoals of professional jealousy. A dispatch to the *New York Times* says that, in order to bar the local American dentists from active connection with the congress, the management adopted a sweeping rule that admission should be extended only to American dentists practising their profession in their own country. This provision effectually slammed the door in the faces not only of the 150 American dentists who practise in German towns and cities, but of several hundred others who are practising in England, France, Austria, and other European countries. When the United States delegation, headed by Prof. T. N. Brophy of Chicago, arrived on the scene and heard of the ban placed upon their compatriots residing in Europe, they caused the management to understand that a painful scene might ensue on the floor of the congress if the rule was enforced. It was thereupon formally relaxed, but those at whom it had been aimed refrained, of course, from accepting the tardy hospitality of the congress. There was much disappointment over the inability of Prof. Brophy of Chicago to take part in the congress, owing to a painful fall which he suffered in his apartment at the Hotel Kaiserhof. Among American participants in the congress were Dr. Frank J. Haessler of Chicago, Dr. Jackson of New York, Prof. Gaskill of Philadelphia, Dr. Crawford of Nashville, Dr. Hoff of Ann Arbor, and Prof. Potter and Prof. Boardman of Harvard University. The American delegation was entertained at a banquet by the local American dental club on Wednesday evening, and Thursday at noon there was a reunion at luncheon of all the Harvard dental graduates attending the congress.

The Colorado State Medical Society will hold its thirty-ninth annual convention at the Hotel Stanley, at Estes Park, Col., on September 14, 15, and 16, 1909. The president of the society is Dr. P. J. McHugh of Fort Collins, the secretary, Dr. Mellville Black, Majestic Building, Denver, and the chairman of the arrangement committee, Dr. J. Nichol Vroom of Denver.

Physician Shot by Patient.—Dr. Shirley N. C. Hicks of Jamaica, N. Y., was shot in the thigh recently by a neurasthenic patient. While Dr. Hicks was making a professional call on the patient she left the room, and a moment later Dr. Hicks, hearing a shot, followed. In an effort to wrest a revolver from the hand of the overwrought patient it was accidentally discharged and Dr. Hicks received the bullet in his thigh. The woman then shot herself in the chest, shattering the sternum. Dr. Hicks' wound is not dangerous.

Memorial to Dr. J. Edward Turner.—The Society for the Study of Alcohol and Other Narcotics has issued an appeal for funds to erect a monument at the grave of Dr. J. Edward Turner at Wilton, Conn. Dr. Turner was a pioneer in the modern crusade against alcoholism and was the founder of the first inebriate asylum in the world, at Binghamton, N. Y. He died penniless and his grave is unmarked. The chairman of the committee in charge of the memorial is Dr. T. D. Crothers of Hartford, Conn., and the treasurer Dr. L. D. Mason, 171 Joralemon street, Brooklyn, N. Y. Each subscriber to the fund, which it is hoped will reach $600 to $700, will be presented with a copy of Dr. Turner's book "History of the First Inebriate Asylum in the World."

Obituary Notes.—Dr. Radcliffe Crocker of London, England, died on August 22, 1909, at Engelberg, Switzerland. Dr. Crocker was a graduate of the University of London in 1875, and had been a Fellow of the Royal College of Physicians since 1887. At the time of his death he was Physician to the Skin Department of the University College Hospital and one of the best known dermatologists of England. He was vice-president of the British Medical Association and a corresponding member of most of the leading dermatological societies of the world.

Dr. Albert Beach Whitney of New York City died at his home on August 30, 1909, of pneumonia and heart failure, at the age of 71 years. He was a graduate of Columbia College in 1861 and of the Pennsylvania Medical College in 1863.

Dr. James O. Ackerman of Fond du Lac, Wis., died on August 25, 1909, aged 68 years. He was a graduate of the Hahnemann Medical College of Chicago in 1877 and had practised in Fond du Lac for twenty-eight years.

Dr. John A. Allendorf of Charlestown, Mass., died at the Carney Hospital in Boston on August 24, 1909. Dr. Allendorf was a graduate of the Harvard Medical School in 1902.

Dr. Villanova M. Burdick of Dexter, Me., died at his home August 23, 1909, as the result of taking medicine from the wrong bottle while delerious. He was 58 years of age. He was a graduate of the University of Vermont in 1879.

Dr. Robert W. Erwin of Bay City, Mich., died at Washington, Mich., on August 13, 1909, aged 67 years. He was a graduate of the Bellevue Hospital Medical College in 1870, and was a member of the Bay-Arenac-Iosco Counties Medical Society, the Michigan State Medical Society, and the American Medical Association.

Dr. A. M. F. McCullough of Los Angeles, Cal., died at the Pacific Hospital, in that city, on August 19, 1909, aged 56 years. Dr. McCullough was a graduate of the Jefferson Medical College in 1877. He had practised in Wachita, Kan., until 1894, in which year he moved to Los Angeles.

Dr. John W. Rasmussen of West Allis, Wis., died at his home on August 27, 1909, aged 37 years. He was a graduate of the medical department of the University of Wisconsin in 1897.

Dr. George Francis Shears of Chicago died at his home on August 27, 1909, aged 62 years. He was a graduate of the Hahnemann Medical College in 1880. In 1889 he became Professor of Surgery and in 1900 president of that institution. He was also president of the Clinical Society, the Chicago Homeopathic Society, and the Illinois Homeopathic Medical Society.

Dr. Stephen H. Weeks of Portland, Maine, died at the Maine General Hospital on Sept. 1, 1909, aged 74 years. Dr. Weeks was a graduate of the medical department of the University of Pennsylvania in 1864. He was the founder of the Maine State Sanitarium, and a member of the Cumberland County Medical Society, the Maine Medical Association, and the American Medical Association.

Dr. Charles T. Wilber of Kalamazoo, Mich., died on August 23, 1909, aged 74 years. He was a graduate of the Berkshire Medical College, formerly of Pittsfield, Mass., in 1860, and was a member of the Kalamazoo County Medical Society, and the Michigan State Medical Society.

Dr. Hamlet Sharp Garland of Oskaloosa, Iowa, died August 27, 1909, of appendicitis, aged 26 years. He was a graduate of the Kentucky University Medical Department in 1904, and a member of the Mahaska County Medical Society, and the Iowa State Medical Society.

Dr. Mark Davis of Beatrice, Neb., died at his home August 26, 1909, aged 95 years. Dr. Davis practised medicine for many years in Indianapolis and other cities of Indiana, but since moving to Nebraska, in 1880, has lived in retirement.

Dr. Nicholas T. Glenn died at Philadelphia on September 1, at the age of 25 years. He was a graduate of Jefferson Medical College in the class of 1907.

Dr. Franklin Allen Gauntt of Burlington, N. J., died September 7. He was graduated from Jefferson Medical College in the class of 1886.

Sixteenth International Medical Congress.

(Special Cable Report to the Medical Record.)

Budapest, September 4.—At the general session, held September 1, Professor Jacques Loeb of California delivered an address on "Artificial Parthenogenesis and Its Bearing upon the Physiology and Pathology of the Cell." In this address he took the stand that in chemistry was to be found an explanation of all vital phenomena, and he hazarded the assertion that there was no inherent impossibility in creating life in a mass of inert organic matter by means of chemical processes. He related how he had succeeded in hatching out the non-fecundated eggs of the sea-urchin by immersing them in certain solutions, and described a series of experiments he had made in artificial fecundation in the endeavor to fathom the secret of the physio-chemical nature of this process.

At this session the announcement was made that Dr. Louis Livingston Seaman of New York City had made an offer of one hundred pounds ($500) to the Congress to be given to the author of the best essay on the "Military Sanitary Service," the award of the prize to be announced at the Seventeenth International Congress. This offer was accepted by the Congress, and it was stated that the details as to the conditions of competition would be announced later.

At the Common Session, held this day, there was a general discussion on "Immunity," all the papers on this subject which had been offered in the different sections being brought together here. The principal speakers were Gruber of Munich, Bordet of Paris, and Detre of Budapest. Among the other papers on the program for this most important and interesting session were contributions by Bezredka of the Pasteur Institute, Paris, Ehrlich of Frankfort, Fränkel of Vienna, Kraus of Vienna, Landsteiner of Vienna, McArthur of Chicago, Morgenroth of Berlin, Neuberg of Berlin, and Neufeld of Berlin.

A gala performance was given in honor of the Congress at the National Theater, and a reception was held by Archduke Joseph, acting in place of the Emperor, at the Royal Palace in Buda.

One of the most interesting discussions was that held at the Common Session, on Thursday, September 2, on "Appendicitis." At this meeting were collected all the papers on this subject offered to the sections on Surgery, Gynecology, and Internal Medicine. The discussion became one in which conservative Europe was arrayed against radical, or rather progressive, America. The continental physicians, led by Sonnenburg of Berlin, in a paper entitled "The Early Operation in Appendicitis," contended that operation was seldom called for, certainly not so frequently as American writers would lead us to suppose. Sonnenburg reported on 300 cases of undoubted acute appendicitis in which the attendant had refrained from operation and in which a perfect recovery had been obtained. He maintained that early operation was not essential in acute appendicitis and that the patient's condition in recovery following the conservative plan of treatment was much better than it was when the appendix had been removed. The surgical, or operative, side was taken by John B. Murphy of Chicago and Robert T. Morris of New York, who spoke strongly

and with emphasis of the duty of operating in the early stages, before such extensive damage had been done as seriously to jeopardize the life of the sufferer or to expose him to the dangers attendant upon a recurrence of the inflammatory process at a time or in a place when skilled surgical help could not be obtained. The speaker quoted the statistics put forth by the advocates of both methods of treatment and showed that those of the Americans, in cases in which early operation had been resorted to, were more favorable than the European figures of the results of the so-called conservative or expectant plan of treatment.

At the general session held this day Laveran of the Pasteur Institute, Paris, the discoverer of the blood parasite of malaria, delivered a long but interesting address on Exotic (Tropical) Pathology. Following this the presidents of the different sections entertained the members of their sections at private soirées in their homes.

On Friday, September 3, Professor Max Gruber of Munich delivered, before the general assembly, an address entitled: "Heredity, Selection, and Hygiene."

The closing session was held in the great banquet hall of the large and imposing Moro-Romanesque "Redoute Building," on Saturday, September 4, at 10 A.M. It was then announced that the Committee, consisting of the presidents and secretaries of the national committees as well as of the president and general secretary of the Congress, meeting on Tuesday, had selected London as the place of meeting of the Seventeenth International Congress, Professor F. W. Pavy having been nominated to the presidency. It was decided also to establish a permanent International Committee, to meet at The Hague, to decide on matters relating to future international congresses.

Count Albert Apponyi, Hungarian Minister of Public Instruction, addressed the Congress on behalf of the Government, speaking in warm and appreciative terms of the work done by the members. He said the people of Budapest and of Hungary were grateful for the large attendance of foreign physicians, regarding their presence in such large numbers as a graceful compliment to their city and country. The usual speeches of farewell were then made by the official delegates of the various countries, who, speaking for their respective governments, thanked most warmly the Hungarian Government and the authorities of Budapest for their hospitality and for all they had done to render pleasant and instructive the stay of the foreign members and to forward the success of the Congress.

This Congress, while marked by no startling or sensational announcement, may be said to have been a decided success; the general sessions as well as the section meetings were well attended, the papers were in general good though not extraordinary, and the entertainments were most enjoyable.

Abdominal Myomectomy.—S. Pozzi gives the indications for abdominal myomectomy thus: In young women when the fibroma is single, not very large, does not penetrate the uterine cavity, and when the adnexa are healthy; myomectomy may also be done when there are several small myomata; in older women it may be done if the other genital organs are healthy; it should be preventive and complementary to other operations in young women, even if the nodules have given rise to no symptoms; it should rarely be done in pregnancy on important indications, and with the greatest care.—*La Presse Médicale.*

Correspondence.

THE TWELFTH INTERNATIONAL ANTI-ALCOHOLIC CONGRESS HELD IN LONDON.

To the Editor of the Medical Record:

Sir:—The Twelfth International Anti-Alcoholic Congress, which was held in London from July 18 to 25, 1909, was chiefly remarkable for the Government recognition of the alcoholic problem and the number of leading physicians who took part in the exercises. It was a surprise in diplomatic circles to know that the intensely conservative Government of Great Britain should not only invite the Congress to hold a session in London, but take a very active part in promoting and recognizing it as a national event. The Duke of Connaught was made honorary president. Among the officers were over thirty leading physicians and medical teachers of the country, and a host of lords, bishops, and members of Parliament. The Home Secretary sent formal invitations to sixteen different nations of the world to be officially represented by delegates to this conference. They all responded. Most of them sent leading medical men and Government officials. Of those appointed by this country the following medical men were present: T. D. Crothers of Hartford, Conn.; C. H. Hughes of St. Louis; Reid Hunt of the Public Health and Marine-Hospital Service, and Surgeon Pleadwell of the U. S. Navy. Temperance societies, church organizations, reform movements from all over the world were represented by the very best men and women of these organizations, and the number registered was between 1,400 and 1,500, making it the largest gathering for the discussion of the alcoholic problem ever held.

The central purpose of this Congress is to discuss the alcoholic problem as a sociological hygienic, medical, statistical, economic, and scientific one. No resolutions or conclusions concerning disputed facts are endorsed by the Congress as a whole, but the Congress is simply a gathering for the study of the subject and not for the teaching or promotion of any particular dogma, theory, or set of facts. The term "anti-alcoholic" expresses the plan and purpose of the Congress to consider the evils from the use of alcohol and the methods of prevention, together with such possible causes as may be neutralized and overcome by hygienic measures. No questions of morals or ethical theories are endorsed or made prominent. Each person is free to express any personal opinions and the reasons for them, as a simple contribution.

The interest manifested by the English Government was displayed in receptions given to the delegates by one of the home secretaries, the Lord Chief Justice, the Lord Mayor of London, the Bishop of London, and other dignitaries.

The Congress consisted of morning sessions in Kensington Town Hall and the reading of formal papers, followed by free, open discussions, carried on in French, German, and English and interpreted from the platform. Several afternoon and evening sessions were devoted to scientific papers and technical discussions of alcohol, which were very largely attended. Among the many medical papers that presented facts that were new was that of Dr. Holitscher of Karlsbad on "Alcohol in Lobar Pneumonia and Enteric Fever." His studies were based on statistics of forty-seven hospitals, in eighteen of which a plan was followed of the alternate use of alcohol in similar cases, in order to determine in which the progress was the best and the mortality the least. In 238 cases of pneumonia treated with alcohol the death rate was 24 per cent.; among 248 cases treated without alcohol there was only 21 per cent. mortality. Of 47 cases complicated with delirium tremens 21 were treated with alcohol and 15 died; of 26 patients of the same class treated without alcohol the mortality was only 0. Of the 161 typhoid fever cases 80 were treated with alcohol, of whom 15 died; in 81 treated without alcohol the death rate was only 12. This paper was discussed at some length by many leading physicians.

The Norman Kerr lecture on "The Influence of Alcohol on Immunity" was given by Dr. Laitinen, the director of the Hygienic Institute of the University of Helsingfors. This was based on the result of experiments on 223 persons to determine whether alcohol increased or diminished the resistance of the human red blood corpuscles to serum and toxins, also whether

the use of alcohol conferred any immunity on the person who used spirits. His conclusions were that the normal resisting power of the blood serum was less in the case of alcohol drinkers than in that of abstainers, also that the bactericidal power of blood serum against typhoid bacteria was much less in drinkers than in abstainers. He concluded that alcohol in small doses exercised a prejudicial effect on the perfected mechanism of the human body. Prof. W. H. Rivers of Cambridge described the effect of alcohol on the human body in health, when given in disguised form. The object was to show whether there was a greater increase of energy and stimulation from its effects. The results of his studies were negative and simply showed a reaction which could not be called stimulation or increase of energy. Dr. Clouston of Edinburgh, in a paper on "The Resistive Power of the Human Brain Against Alcohol, and its Limitations," showed that while in healthy, sound brains the resistance was very pronounced, it was very uncertain and doubtful in defective and abnormal conditions; also that no one could determine what the resistance was, hence the great danger of using alcohol in any form.

Prof. Henschen of Stockholm, in a paper on "Alcoholism and Tuberculosis," concluded that there was unmistakable evidence of an intimate relation between the two, and that alcohol could never be used as a remedy without increasing the fatality. He presented elaborate statistics and conclusions in support of his view.

Dr. Lagrain, the superintendent of the Insane Asylum at Paris, in a paper on "Alcoholism and Insanity," concluded that alcohol was more poisonous than lead or phosphorus and was both directly and indirectly responsible for a large amount of dementia and mental feebleness. Dr. Crothers of Hartford followed in a paper on "The Insanity of Inebriety," in which he urged that habitual users of alcohol should be considered as insane. Dr. W. F. Mott, the pathologist of the London Asylum, in a paper on "The Effects of Alcohol on the Nervous System," illustrated by the screen, showed that structural changes of the brain and spinal cord in which digestion, assimilation, excretion, and circulation were disturbed were the direct result of alcohol. He also showed that alcohol favored the production of toxins which combined and produced conditions in the highest degree destructive to the brain integrity, and this was possible from small quantities of spirits.

A very elaborate paper on "Criminal Inebriates" was read by Prof. G. Aschaffenburg of Cologne. He described the damage to the brain circulation from small quantities of spirits, the danger from these transient derangements becoming permanent, particularly where there was inherited mental inferiority, and urged that the damage which alcohol produced on the brain should be studied in the question of treatment and legal penalties.

The Lord Chief Justice of England declared, at a reception, that his forty years' experience at the bar and ten years as a judge had proven beyond question that 90 per cent. of the crime could be traced to alcoholic drinking, and that he was convinced that no single agent was more active as a cause than this.

A number of other papers were devoted to questions of heredity, the action of alcohol on the offspring, and alcohol and its effects on children and on the home.

Miss Stoddard of Boston, the head of the Scientific Federation Bureau, described at some length the effect of teaching the dangers of alcohol in the common schools, and a number of continental physicians followed, giving some startling facts and urging that this phase of the subject be made more prominent.

Abstracts of each paper were published in two different languages, so that it was possible to follow every reader and get a fair idea of what he was talking about. The daily press gave very large space to the various subjects, and there was something startling in the fact that so large a gathering of men and women should spend a whole week discussing topics that as a rule are only heard in reform circles. The dominant idea through all the addresses, papers, and discussions was that alcohol should be regarded as a narcotic and depressant in its effects on the body, and not as a stimulant, and that as a beverage it is extremely dangerous. Beyond that, its effects as a remedy are still uncertain, with a rapid accumulation of facts from laboratory studies and clinical experience which point out its prominence as an active cause of disease.

Another fact which was brought out indirectly was that the evils of alcohol could be prevented, and from a larger knowledge of the subject it was possible to eradicate and break up many of the great degenerations which follow from this cause.

A volume of transactions will be issued containing all the papers, many of which are already appearing in the various journals. The medical journals gave a very candid review of the proceedings and all were impressed with the fact that this was the beginning of a great new movement that was destined to occupy a very large place in the scientific development of the future.

The Queen of Holland formally invited the next Congress to hold a meeting at The Hague in 1911. This was accepted. The real significance of this Congress was the beginning of a revolution in public sentiment concerning the use of alcohol, particularly in continental Europe, where spirits have been used from the earliest times. It was pleasant to note that all the great leaders of this movement recognized and acknowledged the advanced work done in America, and the tremendous efforts to overcome some of the evils that are prominent.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RED CROSS SOCIETIES AND TERRITORIAL FORCE—CHLOROFORM DANGERS—CONFERENCE ON THE BLIND—EARLY NOTIFICATION OF BIRTHS—UNPAID MEDICAL PUBLIC SERVICES—ANGLO-AMERICAN MEDICAL SOCIETY—DARWIN EXHIBITION—OBITUARY.

London, August 20, 1909.

The Red Cross Society and the St. John's Ambulance Association are to be affiliated to the Territorial Force, and the members of both seem to be gratified with the decision of the Army Council. To the men's voluntary aid detachments will be assigned the duty of converting farms, houses, and buildings into temporary hospitals, of preparing carts and stretchers for the removal of patients, of fitting up rolling stock for the transport of the wounded by rail, of making local arrangements for transporting the sick and wounded from the railway stations to the hospitals, and of disinfecting buildings. Women's voluntary detachments will be employed in forming railway rest stations, in preparing and serving meals and refreshments for the sick and wounded on the journey from rail to hospital, and in taking temporary charge of cases too severe for removal. They will also look after the cleanliness of the hospitals and render any nursing service that may be needed. It is pointed out that there are numerous ways in which all classes of the community willing to organize and train themselves during peace may give patriotic aid whenever actual need arises. The scheme is really in existence in skeleton form in the Red Cross Society and its branches throughout the Kingdom, already 90 in number. There is a branch, too, in Canada, and another at the Cape. Each member undertakes a certain financial guarantee, and the fund thus available at present exceeds £12,000, which, in emergency, would no doubt be enormously increased by donations.

Several deaths from chloroform have occurred lately and have led to numerous comments and questions as to the relative dangers of various anesthetics. At an inquest on a child who died in the Ormond Street Hospital it was stated by the house surgeon that the patient recovered quite normally from an operation, but on the following day symptoms appeared which were suggestive of delayed chloroform poisoning and proved fatal. It was also stated that the *post-mortem* showed that death was due to heart failure, resulting from that cause. The Coroner remarked that these cases were very rare, as only about one in two years came to his notice. A little while ago society was greatly perturbed by the sudden death during anesthesia of a lad of 13, an heir to a title. He had been carefully examined before administration, and nothing abnormal was discovered except the adenoids, which were to be removed. A mixture of two parts of ether to one of chloroform was used, and the little fellow said: "This is nice. I like it." Just as the operation was completed breathing ceased, and every known method was tried to restore it, but with no effect. The autopsy was made by Dr. Trevor, the pathologist of St. George's Hospital, who ascribed the death to status lymphaticus, about which he admitted little is known; but it produced instability of the nervous

centers, and any injury was likely to cause death in patients suffering from it. He had never seen so decided a case as this.

Dr. D. S. Thompson took the view that all children with adenoids were inclined more or less to the status lymphaticus, and regarded removal of adenoids or tonsils as serious operations in them, on account of the obstruction to the respiratory passages. The accustomed lowered breathing reduced the vitality. I quote this case, although the death was thus attributed solely to the operation, because many medical men may doubt whether the anesthesia is to be altogether exonerated. It is also suggested to me that adenoids may be removed without anesthesia; indeed, I have been informed by a well-known specialist that he does not resort to the administration of any anesthetic in the performance of this operation.

At another inquest, held at Guy's Hospital on the 30th ult., the Coroner, Dr. Waldo, stated that out of 41 deaths from anesthesia into which he had had to inquire 33 were due to chloroform, or to etherial mixtures containing it; the other eight to ethyl chloride. The figures are suggestive, but we have to consider in what number of cases the two anesthetics were employed before we can determine their relative mortality. No doubt ether is used at Guy's. Dr. Waldo has not had one inquest in which it was used there; but the authorities might very well let us know how often it is employed. Some of our anesthetists have almost entirely discarded chloroform for ether, and, although more trouble and skill may be demanded to attain equal results, none of them would be unwilling to devote his energy to the safer drug if they were quite convinced of its relative safety. The question is increasing in importance, and some are asking how it is that in Ireland, where the use of ether is almost always resorted to, deaths are very rare, while fatalities are more common in London, where chloroform is so much more frequently given.

The committee appointed last year at the International Conference on the Blind has issued its report. It concludes that the early notification of births is an urgent matter; that "ophthalmia of the newborn" should be added to the compulsory notifiable diseases; that more definite teaching on the seriousness of eye diseases in children should be given to midwives; that the Central Midwives' Board should issue more stringent instructions on the danger of "whites" in lying-in women. The committee also suggests that more definite returns be made in the census in regard to the causes of blindness.

No doubt early notification of births is desirable in this as in other cases. It is compulsory where the local authority adopts it; but it may be administered with a zeal that leads to injustice. This was seen last week in Paddington district, where a dozen parents were summoned for not notifying within 36 hours. They all pleaded ignorance that the law had been adopted, which seems to indicate that the Council had not made its action fully known. The lawyer for the prosecution suggested that it would be a good plan to summons the doctors, as the inconvenience to them would perhaps make them take the trouble to notify themselves. Lawyers never seem ashamed of insulting suggestions; but it is surprising to notice that the magistrate seemed to agree with this one. If notifications of all sorts, which have been brought about by the recommendations of the profession, are to be used to further such oppression it may lead to a refusal on the part of the profession to agree to any more gratuitous services to the State.

This question of payment for medical services rendered to the State was, I hear, pretty fully discussed at Belfast in reference to the treatment of school children found, on inspection, to be in need of it. Different proposals were made, that of establishing school clinics being supported by a considerable number. On the other hand, the plan of utilizing hospitals and dispensaries was pretty freely condemned by the general practitioners, although hospital men were not altogether opposed. It seems obvious that if the educational authorities subsidize voluntary charities the honorary officers must do the work, and if paid their offices will not be honorary, and the neighboring practitioners will be injured. Now the London County Council has begun this plan with regard to "a small number" to see how it answers. We may therefore expect to see it extended. As arranged, some children are to be treated for nothing; others for a small sum, and there is no attempt to solve the problem which is held to be so important to parents and the rate-payers. It was stated that in some parts parents with incomes of £200 to £300 a year sent their children to the board schools. It may well be asked by the profession at large, as well as by those immediately interested, whether such persons are to receive gratuitous medical treatment while the doctors living near them starve on a less income?

Mr. Overy proposed a resolution, expressing a hope that the staffs of hospitals would do all in their power to prevent abuse of voluntary charities, but no one seems to expect much from this, for the staffs appealed to have never helped the general practitioners in their campaign against "hospital abuse." So with the committees of management, always ready to take financial aid from any source. But in this case they may be restrained by a fear that the County Council, if it contributes to any sensible amount, is certain to demand representation and eventually exact control. Sir Victor Horsley, who always speaks his mind decisively, said the attempt of the County Council was ridiculous, and its folly was shown in the fact that only a few hundred cases had been provided for out of the 70,000 to 80,000 children in need of treatment. Another speaker said that at Cardiff no less than 38 per cent. of defectives were treated at the infirmary. This seems a manifest case of the abuse of voluntary charity, and such facts lead to the assertion by many that parents who can pay should be made to pay, and those who cannot should be referred to the provision of the Poor Law.

At the annual luncheon of the Anglo-American and Continental Medical Society, which was held at Belfast, some of the members from your side were present. Professor Osler took the chair, and in proposing the chief toast, said the society was a valuable bond of union between us; but still more, it gave members the names of physicians abroad to whom they could confidently entrust their patients. Regarding the latter point, however, one observer has remarked that after all the membership of a society of this kind can scarcely be recognized as a guarantee of the ability of a practitioner or his general fitness for undertaking every traveling patient's case.

The centenary of Charles Darwin is being commemorated by an exhibition at Natural History Museum. A very large collection of objects connected with the life and work of the great naturalist has been gathered, and was opened on Tuesday. It is not intended in any way to support his opinions or otherwise, but to illustrate the facts he accumulated and commemorate his devotion to science. Many of the exhibits are more relics of the man than anything else, and excite great interest. It so happens that the centenary occurs at the time when many maintain that his views are under the shadow with which time so often covers theories. German scientists like Dennert and Goette have for some time talked of the collapse of Darwinism, and some of our own have followed them, though with more hesitation.

Sir William Howorth, president of the Archæological Institute, addressing the Cambrian Association on Tuesday last, on taking the presidency in succession to Professor Sayce, said most inquirers still held that man was linked to a great procession of living animals which had marched out of the recesses of time by some process of evolution, but that was nothing more than a working hypothesis. So, to solve the problem of man's origin, we must postulate for him stupendous antiquity. He denied not merely the fact but the possibility of the ice age as usually put forward. Local glaciers might have been larger than now, but as to their traveling and depositing boulders he denied the possibility, and the climatic changes implied were equally impossible to assign to such a cause. He added that the effects usually attributed to the action of ice were the result rather of rapid, violent movement of enormous masses of water. But whether caused by ice or water the drifts were subsequent to the origin of man.

Lieutenant-Colonel V. Doig, late of the Army Medical Department, died recently. He qualified in 1863 and entered the medical service of the army the same year, obtaining promotion in 1873. He served in the Ashantee war, 1873-1874, for which he was awarded the medal, and retired from service in 1883 as surgeon lieutenant-colonel, receiving further the honorary rank of brigade surgeon.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 26, 1909.

Heart Disease in Infancy and Childhood.—John Lovett Morse calls attention to the fact that the volume and weight of the heart relative to the body weight are greatest in the new-born, sink rapidly in the first and second years, increase again for a time, are smallest in the years before puberty, and increase rapidly during puberty. The caliber of the arteries in early childhood is relatively large in comparison to the volume of the heart. The diameter of the veins in relation to that of the arteries is smaller in childhood than later in life. These peculiarities explain low blood pressure, rapid circulation, and frequent pulse of infancy and childhood, and also the fact that cardiac physical signs vary very materially at different periods of infancy and childhood. The cardiac impulse is rarely visible and frequently not palpable in early infancy. Percussion is best performed in infants in the recumbent position and comparisons must always be made with the child in the same position. It is impossible to determine accurately the area of dulness in infancy, the usual mistake being to make the area too large. Great care must be exercised in diagnosing an accentuation of the second pulmonic sound. Reduplication of the second sound is not uncommon under normal conditions. If this alone occurs it is not necessarily pathological. Among the general peculiarities in the physical signs of cardiac disease in infancy and childhood are prominence of the precordia. Murmurs are often heard over large areas. Thrills are more common than in later life. Cardiac disease interferes with the growth of other organs and retards development in general. The tendncy to recovery is greater in earlier than in later life. The presence of cardiac disease in infancy or early childhood without the history of some disease likely to cause cardiac disease is strong evidence in favor of a congenital lesion. Cyanosis and clubbing of the extremities without signs of venous congestion in other organs and without heart murmurs or other evidences of disease sufficient to cause them are strong evidence in favor of congenital lesions, as, also, are loud murmurs without enlargement of the heart. Diastolic murmurs are practically never congenital. Contrary to general teaching, anemic and functional murmurs are not uncommon in infancy. When the murmurs are anemic there is no enlargement of the heart and no thrill. The treatment of congenital heart disease is entirely symptomatic. Insufficiency of the heart muscle calls for digitalis. Severe symptoms are treated as in acquired heart disease. Sudden attacks of suffocation and convulsions are best avoided by the use of bromides. In diagnosing acute endocarditis the murmurs most often mistaken for those of acute endocarditis are the cardiopulmonary. They are to be differentiated by their variability with respiration and with the pressure of the stethoscope. Slight pressure increases them; strong pressure stops them. The one important thing in the treatment of this condition in childhood is rest; stimulants are seldom needed. Children with chronic valvular disease must be kept under constant observation. Every detail of their lives should be regulated, the fundamental principle being that there shall be no prolonged strain. When compensation is failing the treatment is the same as for adults. In myocarditis and myocardial insufficiency the one important thing, both as a prophylactic measure and after their development, is rest. Alcohol is useless. Strychnine helps some. Digitalis cannot act on a degenerated muscle. Nitroglycerin is dangerous, predisposing to vasomotor paralysis. Massage of the abdomen, ice to the abdomen, caffein and adrenalin subcutaneously are most useful. Functional disturbances of the heart are liable to appear at the time of puberty, and it is important to bear in mind that there is often an enlargement of the area of dulness and murmurs, probably due to relative insufficiency of the mitral valve, which, added to the usual signs and symptoms, make it easy to mistake the condition for organic disease. Acute pericarditis is very unusual in infancy, is less frequently secondary to pneumonia and more often tuberculous than in later life. The tendency to effusion is greater than in adults. The symptoms are surprisingly latent in infancy and early childhood. The treatment is essentially the same as in later life. Chronic adhesive pericarditis is far more common than is usually supposed. It most often follows plastic rheumatic pericarditis, but is occasionally tuberculous in origin. There is nothing distinctive about the symptoms of this condition; it causes in some instances a peculiar form of cirrhosis of the liver.

Work for Patients as an Immediate and Ultimate Therapeutic Factor.—Frederick L. Hills describes a system of work which has been in operation for several years at the Massachusetts State Sanitarium at Rutland, and gives some of the results of this system. For economic reasons the patients were expected to do a certain amount of light work. During the first week of residence no work is allowed, and the pulse and temperature are carefully watched. After the first week if the temperature is normal a short walk of ten or fifteen minutes once or twice a day, if attempted, and the amount of exercise gradually increased until the patient is taking an hour twice daily. All patients who can exercise to this extent are expected to work from one-half hour to two hours daily at light tasks, heavier tasks being gradually imposed as the patient demonstrates his ability to perform them. At present some degree of work is done by 51 per cent. of the patients. In this way a large part of the working force of the institution is recruited. Dr. Hill believes that they have demonstrated the value of work as a therapeutic measure to be even greater than as an economic measure. During the past five years, in 27 patients, who played baseball in addition to their work, and in whom the disease was incipient in 12 and moderately advanced in 15, and whose condition at the time of discharge showed 3 apparently cured, 11 arrested and 13 improved, the subsequent history shows that 81.4 per cent. are to-day doing full-time work, two have had relapses and are working on part time, and three are dead—two because of intemperate habits. The subsequent history of 30 patients who worked four and one-half hours during their sanatorium residence shows that 70 per cent. are doing full regular time work, 16.6 per cent. have had relapses, and four are dead. In comparison with these the subsequent history of 365 patients discharged in 1905 shows that 56 per cent. are now working. Of 25 board working patients discharged during the same time 68 per cent. are now working. Although the comparison is not entirely fair, as the workers are picked ones, the figures help to demonstrate the ultimate result of work in building up the resistance of the patient. Relapses among this class are comparatively infrequent. Success in the therapeutic application of labor cannot be obtained without system and careful supervision. Obedience, supervision, and graduation must be the watchwords. The tendency of the "rest cure" is to make dependents of our patients; but by carefully prescribed labor we can return a greater number to their homes independent and self-supporting citizens.

The New York Medical Journal, August 28, 1909.

Tuberculosis of the Knee Joint.—Irving D. Steinhardt states that in regard to tuberculous disease in bone and joints, knee joint disease comes third, tuberculous disease of the spinal column and the hip joints being respectively first and second. About 50 per cent. of the cases of tuberculosis of the knee joint occur from the second to the sixth year; its occurrence is quite frequent up to the twelfth year and not infrequent up to the twentieth year. The seat of the disease is usually in the epiphysis of the femur or tibia and less often in the synovial membrane. The salient features of the disease which help us in a proper diagnosis are: (1) A limp developing from no apparent cause, such as a fall or injury; (2) pain and sensitiveness without redness and immediate large swelling in the knee joint only and without the constitutional reaction of a rheumatic nature; (3) change of contour in the joint, and particularly if accompanied by atrophy; (4) slow and insidious development of a flexion deformity; (5) "night cries" (unguarded movements that cause a sharp sudden pain, accompanied by an involuntary cry of suffering); (6) persistent morning stiffness confined to one knee joint; (7) a sudden disposition of the patient to avoid activity and to guard the limb against quick change of position; (8) the appearance of these symptoms after infectious disease, or after trauma; (9) a positive tuberculin reaction in a suspicious but doubtful case in a child under five years of age where other tuberculous lesions can be practically excluded; (10) a positive *x*-ray picture. At present stronger evidence of real serious tuberculous disease must be found to condemn a patient than merely a positive tuberculin test. Tuberculous disease of the knee joint must be carefully differen-

tiated from rheumatism, gonorrheal arthritis, scurvy, hemathrosis, hip disease, injury, rachitis, synovitis, syphilis, Charcot joint, Still's disease, new growths, and nervous affections. With no tuberculous involvement except the knee joint the prognosis as to life is very good; but with pulmonary disease or tuberculous lesions elsewhere the patient is in greater danger. If there is any doubt as to the diagnosis of the case, treat it as a positive one, as early treatment is very important. The best prophylactic measure is correct hygiene during infancy and childhood. The treatment of tuberculosis of the knee joint in children is usually conservative, whereas in adults, in early cases in particular, excision of the tuberculous area is in vogue. Where long continued suppuration is a menace to life amputation may be practised. This latter would be true in children also. As yet our best remedial agent has been old Dame Nature, assisted by allies in the form of plaster of paris and braces of various kinds. Dr. Steinhardt is at present experimenting with tuberculin injections, but is not prepared to praise or condemn this treatment. Conservative treatment consists in immobilizing the knee joint as completely as possible. Experience has shown that the more complete the immobilization the better the chances of preserving joint motion. Plaster of paris and braces may be combined in certain cases. The Bier treatment (hyperemia) should always be used as an adjunct to both methods of conservative treatment. When abscesses occur Dr. Steinhardt uses the circular rubber bandage to cause a general hyperemia of the part, cups the sinus openings with suitable Bier's cups, after which he applies the following ointment to the joint: Ichthyol, 25 per cent.; iodine, 5 per cent.; lanolin, 20 per cent.; petrolatum, q.s. 100 per cent.

Contribution to the Study of Blood Pressure in General Paresis.—A. Schmiergeld has measured the blood pressure of 40 patients suffering from paresis, taking the pressure in each individual from five to seven times, and accepting the number which figured most frequently as the right one. Among 13 paretics younger than forty years of age, nine had a low pressure, one a normal, and only three had arterial tension above the supposed normal; among 21 paretics, whose ages were between forty and fifty years, nine had a low pressure, six a normal, and only six a high one; finally, among the six paretics older than fifty years four had a low pressure and only two a high pressure. From his observations on this series of cases, Dr. Schmiergeld concludes: (1) To estimate the blood pressure of an individual it is necessary to measure it several times. (2) The blood pressure in general paresis is very variable. (3) In the majority of cases, however, it seems lower than in normal individuals. (4) There exists no relationship between the mood of the paretic and the arterial tension: elated paretics can have a high pressure and depressed paretics a low one.

Journal of the American Medical Association, August 28, 1909.

Molluscum Contagiosum.—F. C. Knowles reports an epidemic of 59 cases of this disease that occurred during the year 1908 in the St. Vincent's Home, containing about 350 children. He gives a study of the literature, including brief résumés of the already recorded similar institutional epidemics, and the inoculation experiments that have been performed. His own experiments in this line were two in number. One of them was absolutely negative and the other, while at first apparently typical, soon dried up and disappeared. In the culture experiments made by him, two organisms were found, one the *Bacterium aerogenes*, and the other apparently the *Micrococcus salivarius*. His summary of the study is given as follows: "Molluscum contagiosum usually attacks the face, in a majority of the cases on, or in close proximity to, the eyelids. Children are more susceptible to the disease than adults. It is difficult to explain the present or other epidemics on any other theory, except that the disease is contagious. The cause of the disease is, unfortunately, still to be determined; although a microorganism, usually a coccus, has been found in a few cases. The incubation period is undetermined; from the experiments so far carried out, from a few weeks to many months. The skin apparently does not have to be broken for the infection to occur, but this point is still undecided."

Staphylococcus Inoculation.—H. R. Varney reports on experiments with polyvalent staphylococcus serums in cases of staphylococcus infection, which he has found to be efficient, especially in multiple furunculosis and carbuncle. Rarely has a new lesion developed after the first inoculation. His conclusions are substantially as follows: Polyvalent staphylococcus stock suspensions given in appropriate doses have a decided value in certain localized rebellious infections of the skin. Their administration is practically safe, causing prompt cessation of the active infection and immunizing the patient against its recurrence for a more or less prolonged period. Clinical observations serve as guides as to the time for reinoculation and simplify the difficulties met with in opsonic methods. The appropriate standard for size and frequency of doses have been previously established from opsonic estimations on laboratory patients with light infection. Failure to immunize the patient artificially may be due to an abnormal condition of the skin, non-specific bacterial suspension, or incorrect dosage. Much time is saved in the use of these stock suspensions by the elimination of opsonic indices and by the assistance derived from other therapeutic measures. Less suffering, less deformity, less danger of systemic infection, and less liability to recurrence are the advantages from the use of bacterial suspension as a therapeutic agent.

Chloroform in Phthisis.—J. Walsh objects to the use of ether in tuberculous cases, especially active tuberculosis of the lungs. During the past six years he has never allowed his patients thus affected to be operated on under ether if he could possibly prevent it, and he has never seen any bad results that could possibly be attributed to chloroform in these cases. During the same period he has seen a number of patients manifesting active tuberculosis of the lungs, which activity appeared from the history to be due either to the operation or to the ether. He reports several cases in which chloroform not only did no harm but seems rather to have a beneficial effect, and one of nitrous oxid gas anesthesia which has a similar outcome. Two cases of damaging after-results from ether anesthesia are also reported. While a mere statement of the cases makes it appear that chloroform might be even somewhat curative, as asserted by Holmes and Woodcock of London, he is not ready to advocate it as such. He does, however, believe that in case of necessary operation with anesthesia in all cases of tuberculosis of the lungs, or where it may be suspected to exist, chloroform and not ether should be the anesthetic.

The Tonsils.—C. M. Robertson describes in detail the anatomy and development of the normal tonsil and its variations and relations, and also gives the facts as known as to its physiology. At birth the tonsil is so small as to be unimportant. It attains its full development by the sixth or eighth year and then begins to atrophy. By the age of twelve or fourteen it should have disappeared and should show only as a cicatricial mass between the palatine pillars. Any tonsil that is markedly visible after that age may be considered pathological. Clinically, nearly all children at six have adenoids and enlarged tonsils, and at eight probably 85 per cent. have them. When they exist, pathologically, all kinds of infections may occur. Some authors claim that the tonsil has a part in digestion, but experiment does not prove this and Stöhr claims that they have a phagocytosis action, which the author does not credit. If the normal tonsil is removed *in toto* there is no disastrous after effect, but rather an improvement in health owing to an increased freedom of respiration. Robertson thinks that the function of the tonsil is an ancestral or developmental one, and if it has any function it must be one which is active only during the first part of a child's life between the sixth and eighth years, at which limit the gland has passed its acme of usefulness and normally should disappear by atrophy. If it remains, he holds that, after the sixth or eighth year, tonsils are pathologic and only detrimental, in rendering the individual the less able to combat infections. He recognizes the fact that he is making rather a sweeping statement, which may be criticised by some, but he thinks the investigations, so far as published, of the physiology of the tonsil, having been made on pathologic glands, have been from an erroneous standpoint.

Diseased Tonsils.—F. Mayer says that the conditions of the faucial tonsil which call for operative interference are: (1) Simple hypertrophy interfering with breathing; (2) diseased conditions of the tonsils themselves, causing local or constitutional infection. He

takes up these causes in order and gives an account of the results of the giving of attention to the enlarged tonsils in school children in New York City. Some of the children, after operation, showed an improvement of 100 per cent. over their former ability to work and in behavior, from the simple removal of hypertrophied tonsils. Within six months 76 out of 81 operated on at one time had been promoted and were doing well in the advanced grades. Passing to the second cause, he speaks first of the affections of the tonsil itself that indicate the need of extirpation and secondly the constitutional disturbances connected with its disease. The most common of all these in the first category is acute lacunar or follicular tonsillitis, of which the recurrences are sometimes so frequent as to make the children lose much time from their school work. He goes over the literature to a considerable extent of the other various nonmalignant tonsillar diseases, enumerating the various forms. The second class of cases are then mentioned, and he says that the list has become a very formidable one. A careful study of the voluminous literature of the subject does not at all change his opinion, formerly expressed, as to the tonsils as the portal of infection of a large number of very serious conditions which can be averted by prompt extirpation of these organs. He concludes with the statement that it is imperative on the physician to advise thorough extirpation in all cases of unusual hypertrophy, recurrence of inflammation, or any diseased condition.

British Medical Journal, August 21, 1909.

The Infection of Consumption.—C. Theodore Williams examines the various sources of infection in pulmonary tuberculosis and ascertains to what extent they are elements of causation or spread of the disease. In one out of three cases where consumptives married three wives, one wife survived, and out of nine cases where consumptive husbands married twice the last wife survived in three instances, giving a total of thirteen husbands to thirty-one wives, of whom twenty-seven died and four lived in apparently good health. Though it is improbable that inhalation is the principal means of lung infection, there is every likelihood of some infection taking place through the upper air passages, and that the bacilli enter the lymphatics of the mouth and infect the lymphatic glands of this region and the tonsils, which are often the seat of tubercle. The frequent occurrence of strumous submaxillary and cervical glands may be due to this cause. The possibility, and, indeed, probability, of the lungs and lymphatic system being infected through the intestines is proved without doubt, and the converse—that is, the improbability of lung infection by inhalation—is shown by an instructive experiment by Vansteenberghe and Grysez, who submitted rabbits and guinea pigs to an atmosphere laden with fine carbon particles by keeping them in a glass cage in which a lamp fed by turpentine was burning. These observers were justified in their conclusions that physiological anthrocosis is due in such cases to intestinal absorption of particles arrested in the nasal and pharyngeal passages and afterwards swallowed with the saliva and nasal mucus, to be carried to the pulmonary parenchyma by the blood stream. Infection through the skin and mucous membrane by wounds is not a common method of infection, but sundry cases are on record which prove its possibility, and indicate an undoubted danger from that source. He gives the statistics of the Brompton Hospital medical staff resident since 1882. Among the resident medical officers there were no cases of consumption; among the assistant resident medical officers one (from inoculation), and among the house physicians none was affected during residence. Two subsequently died of acute phthisis, when holding resident appointments in hospitals where cases of consumption were admitted, and one was attacked by consumption fourteen years after he had left the hospital and recovered. Concerning the sources of infection, ingestion of tuberculous material by the intestines is the commonest, inhalation by the air passages comparatively rare, except that which occurs in the upper air passages, affecting the lungs through the lymphatics. Infection through wounds of the skin and mucous membrane is not common, but occurs among those who handle sputum and other tuberculous material where proper precautions are omitted. Infection by coition is rare. All infection from consumptive patients can be avoided if the well-recognized precautionary measures are adopted and carried out thoroughly.

Light, Pigmentation, and New Growth.—Wilfred Watkins-Pitchford says that the increase of cancer within the last seventy-five years is perhaps due to diminished protection from light and increased exposure to illumination. Woolen garments have been largely replaced by cotton, and black and brown clothes by those of a light color. Narrow streets and dark houses are no longer tolerated, and suburban life has largely replaced that of the city. Artificial illumination has become greatly more actinic in its character. The habit of snuffing has yielded to the vastly more prevalent usage of smoking tobacco by means of a pipe. A manifest deduction from the principles advanced is that cancer may be prevented by efficient protection of the body from light. Natural protections, such as hair upon the face, should be encouraged. The clothing should be absolutely light-proof. The ventral surface of the thorax and abdomen should be specially protected. The tobacco pipe should be discarded at the age of thirty-five.

Berliner klinische Wochenschrift, August 9, 1909.

Polyserositis.—v. Marenholtz reports a case of this disease in a young man, aged twenty-two years. He was healthy until eighteen. Family history negative. No history of alcoholic excess. At eighteen the disease began with shortness of breath and swelling of the legs, scrotum, and abdomen. He was operated on for supposed tuberculous peritonitis, but no signs of tuberculosis were found. The ascites continued so that the patient was tapped frequently, and finally a puncture wound discharged for many weeks. Pleural effusion occurred, requiring thoracentesis. Serodiagnosis for syphilis in the fluid was negative. He died in collapse. The autopsy showed ascites, hydrothorax, hydrops of the knee, anasarca, atelectasis and compression of the lung, concretio pericardii, cirrhosis of liver, and parenchymatous nephritis. The liver showed the characteristic perihepatitis of polyserositis. The etiology of the case was obscure.

The Etiology of Congenital Torticollis.—Max Böhm says that congenital torticollis may be due to birth trauma of the sternocleidomastoid or to intrauterine shortening of the muscle. In the latter case there may be no evident change in the muscle, and Böhm asks why this shortening occurs. He says that besides a muscular torticollis there may be one due to osseous abnormalities. He says that the condition of transitional vertebræ may occur between the atlas and occiput, causing an ankylosis between the skull and spinal column. This may be of four grades: (1) The mildest grade shows the presence of exostoses which unite the atlas and the occiput. (2) In the second grade the ring of the atlas is more or less fused with the rim of the foramen magnum. (3) The third grade shows, besides a fusion, a partial disintegration of the atlas. (4) In the highest degree the atlas appears merely as a ridge on the surface of the occiput. If these processes of fusion and disintegration occur asymmetrically the result is a torticollis. The author reports several such cases, photographs of the bones being shown. The condition may be diagnosed by the use of the *x*-ray.

Causes of Error in the Estimation of the Opsonic Index.—A. Strubell and Felber have taken up the question as to whether the ideal results obtained by Wright are attainable by others who have not learned the technic direct from Wright or one of his pupils. They acknowledge the great difficulty in estimation of the accurate index, and admit that industrious investigators, even if good bacteriologists, may easily make mistakes. This is especially so when the investigator has not learned the tricks of the technic either directly or indirectly from Wright. As a result of their investigations, however, they do not think the difficulties are insurmountable. Above all things, for overcoming the difficulties, besides a thorough knowledge and familiarity with the tricks of the method, a sufficient degree of technical skill is required, in order to check and control the results. The control must be made from several healthy persons. The limits of variation of the index in normal individuals seem to be narrower than Wright originally stated. In 75 per cent. of the cases it varied from 0.95 to 1.05, and in 95 per cent. from 0.9 to 1.1. The differences between the counts of two sources from the same mixture varied less than 10 per cent. in 92 per cent. of cases. The tuberculoopsonic index of normal individuals varied less than 10 per cent. in 94 per cent. of the cases. One of the most important sources of error is the occurrence of isoagglutinins of the washed corpuscles.

Book Reviews.

Lectures on Hysteria and Allied Vasomotor Conditions. By Thomas Dixon Savill, M.D., Lond.; Physician to the West End Hospital for Diseases of the Nervous System, Welbeck Street, London, and to the St. John's Hospital for Diseases of the Skin, Leicester Square, London; formerly Medical Superintendent of the Paddington Infirmary and Workhouse; Examiner in Medicine in the University of Glasgow; Assistant Physician and Pathologist to the West London Hospital. New York: William Wood & Co.; London: Henry J. Glaisher. 1909.

The author of this book states in his preface that he has taught the views therein expressed for the past twenty years, and that the principal object of its publication is the "elucidation of the pathology of hysteria and the discovery of a rational explanation of its various phenomena." The author has become known to us chiefly through his "Clinical Lectures on Neurasthenia," and we are glad to welcome his views on a subject so little understood as hysteria, a subject, too, on which there are such opposing opinions. Lack of space prevents us from an extended review and criticism. With some of the prevailing opinions of the psychogenesis of hysteria and what constitutes the disease the author evidently does not coincide. Those, for example, of Freud, on the sexual origin of hysteria, he differs from on the ground of his experience of cases not bearing it out, and he condemns Freud's analysis procedure as "hazardous, harmful, and wholly unjustifiable." Then, again, Babinski's limitations of hysterical symptoms to those admittedly psychogenic he disagrees with, believing rather that all the skin, vasomotor, circulatory, and other symptoms "regarded for centuries" as hysterical, are interchangeable with psychogenic hysterical phenomena, and must be considered as together forming one complete entity. The specialist, who finds little trouble in discovering hysterical manifestations and in separating them from those of true organic conditions, is not appealed to so much in the book as are the student and general practitioner, for whom the subject often presents difficulties. The latter will find suggestions, in regard both to diagnosis and treatment, of a helpful nature, together with numerous illustrative cases introduced to make the explanations more clear and applicable to use. The theories of the author respecting the pathology of hysteria are very interesting, though not entirely new and not altogether convincing.

The Philosophy of Long Life. A Translation from the French of Jean Finot, by Harry Roberts. New York: The John Lane Company, 1909.

This book, if it is serious—and there is no internal evidence to show that it is not so intended—must prove invaluable to the psychologist who is making a study of the mental processes in the different races of men. To the dull Anglo-Saxon mind the jubilance with which the author contemplates the feasting of the worms on the dead body is utterly incomprehensible and nauseating. This he calls immorality in the transformation of human flesh into the substance of crawling larvæ in the grave—and he opposes cremation on the ground that thereby the worms are cheated of the feast which is their due. Finot also believes, apparently, in the possibility of man creating living things, and writes at great length, as though more than half inclined to believe in them, the tales of automata and of sentient and living mannikins created by alchemists. Indeed, the writer is apparently ready to believe anything, especially if printed in the newspapers, except the immortality of the soul, for which he gleefully substitutes the immortality of the chemical constituents of the body. After reading this book from cover to cover in the endeavor to find something of scientific or philosophical interest, one is amazed to learn that the French original has passed through fourteen editions.

Common Disorders and Diseases of Childhood. By George Frederic Still, M.A., M.D. (Cantab.), F.R.C.P. (Lond.); Professor of Diseases of Children, King's College, London; Physician for Diseases of Children, King's College Hospital; Physician to Out-Patients' Hospital for Sick Children, Great Ormond Street; Honorary Member of the American Pediatric Society. London: Oxford University Press, 1909.

In this volume Dr. Still has not attempted to give the world a new textbook of pediatrics. Rather he has written out in book form the points in the diagnosis and treatment of the diseases of childhood which have appealed to him during many years of experience in private practice, and with clinical opportunities such as possibly no man in America has been able to obtain, namely, as senior out-patient physician in the oldest, the largest, and probably the most active children's clinic in the world. To those who have had the pleasure of knowing Dr. Still and of watching him at work, each page of this little book will recall the man's personality and remind one of the lightning speed with which he examines his patients, the rapidity with which he brings out and sets aside the common and well-known points of the case, and the clearness, comprehensiveness, and enthusiasm with which he discussses the odd symptoms, the fine points in diagnosis, and his own personal experience in treatment. This same spirit the author has incorporated in this book. It is not systematic and it is not complete. Much of it—that part which the physician with any experience with children already knows—is put in as few words as possible, consistent with perfect clarity, while other parts, and those on the subjects on which one is apt to be in doubt and especially desirous of enlightenment, are gone into in a manner so complete and extensive that little is left to be desired. The articles on treatment are especially full and valuable, as they do not simply lay down the ordinary textbook rules, but tell, and that in detail, the results which the author has obtained and those that have been obtained by his personal colleagues in London. The entire book gives one the impression that a man who has seen much and has done much is telling what he himself has seen and has done, not what he has read of the doings of others. The book is purely clinical, for Dr. Still's work is clinical. The more obscure scientific aspects of disease, which fill most of the German works on pediatrics, are left out. The book is written in a clear, fluent English, which makes it delightful reading. It is in every way a volume which would be a valuable addition to a physician's library, and one which, if once bought, would be apt to spend more time on the reading table than on the book shelf. In the matter of the bookmaker's art, this little book is quite up to the standard of the other products of the Oxford medical publications, and more praise than that is superfluous.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. Part VIII. By Prof. Dr. H. Strauss, Professor of the Third Clinic, Royal Charity Hospital, Berlin. Authorized American Edition. Translated under the direction of Nellis Barnes Foster, M.D., Associate Physician to the New York Hospital; Associate in Biological Chemistry, College of Physicians and Surgeons, Columbia University. New York: E. B. Treat & Co., 1909.

This short monograph is divided into four chapters, as follows: The Differentiation of Gout, the Pathogenesis of Gout, Symptoms of Uricacidemia, and the Therapy of Gout. The book gives in a concise manner the modern conception of the nature and treatment of gout. The author has confined himself to what he considers the most essential points that have a bearing on the practical treatment. As each case of gout has to be treated individually, Dr. Strauss has indicated the different measures that may be of benefit in the management of the disease. Colchicum and its preparations still head the list in the drug department of an acute attack.

Gynecology. Volume IV. of the Practical Medicine Series. Edited by Emilius C. Dudley, A.M., M.D.; Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago, and C. von Bachellé, M.S., M.D., Assistant Professor of Obstetrics, Chicago Policlinic and College of Physicians and Surgeons; Gynecologist to the German Hospital, Chicago. Series 1909. Chicago: The Year Book Publishers, 1909.

The advance in gynecology during the past year has been along the line of more accurate diagnosis and better and more scientific treatment, both medically and surgically. The book is divided into six parts, dealing respectively with General Principles, Infections and Allied Disorders, Malformations and Tumors, Traumatisms, Displacements, Disorders of Menstruation, and Sterility. The question of the liability of malignant complications or changes in fibroid tumors of the uterus was pretty thoroughly threshed out about two years ago in the section of gynecology and obstetrics of the New York Academy of Medicine. The decision arrived at was that malignant disease was just as apt to take place in a patient without a fibroid tumor as in a patient with one. Yet according to the statistics in this book, the danger of malignant change in fibroid uteri increases very rapidly in a person over forty years of age. Quoting from the book: "The probabilities are that malignant change will result in one case in every twenty between the ages of forty and fifty, one case in every eight between the ages of fifty and sixty, and in one case in every four between the ages of sixty and seventy."

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held in New York, May 27-29, 1909.

THE PRESIDENT, DR. S. WEIR MITCHELL OF PHILADELPHIA IN THE CHAIR.

Thursday, May 27—First Day.

President's Address.—Dr. S. WEIR MITCHELL of Philadelphia delivered this address, saying that he would first discuss some matters of general interest to the association and then take up the questions of the nature of nerve force and the deep reflexes, dwelling especially on reinforcement and the theory of overflow. There was a comparative rarity in the proceedings of the Neurological and other associations of matters of therapeutic interest. The present was the triumphant hour of diagnosis, which was the parent of logical, legitimate therapeutics. He said that he would suggest that the association appropriate a single hour or more, as they might desire, for discussion of therapeutic measures. This might be readily done, and in an interesting fashion, by choosing one subject, as the treatment of epilepsy or some other form of disease, or perhaps two or three diseases. It might be found advisable to have each man discuss the subject for two or three minutes and so fill in the hour. For example, how did the members treat their ordinary cases of epilepsy? He would like to know the measures employed for chorea, or what the members did to treat the spastic conditions that followed apoplectic seizures. There might be some ingenuities of thought of which all the rest were not aware. It would be better than listening to so many papers which were chiefly diagnostic or merely observational, without a single thought that was not surgical on the subject of therapeutics, for, after all, what we did in our clinics and consultation rooms was to tell people to do something. He wanted to know what the members said to people about certain diseases. The physiology and pathology of the negro should receive more attention from the neurologists. There was a rarity in the negro of this country of such diseases as chorea, tabes, migraine, and exophthalmic goiter. Considering the relation of the black skin to heat and light rays, there must be in the negro some automatic compensative mechanism for regulating the body temperature other than that which we possess. Therefore, we needed for the negro a new and complete study of the blood in order that we might get clearer ideas as to his immunity from such diseases as yellow fever and malaria. The physiology of persons who had lost large parts of the body by multiple amputations was a subject worthy of a commission of investigators. Long ago he had studied diseases of stumps and the psychics of lost limbs, but the subject in recent years had been neglected. He next took up one of the two main subjects of his address—neural energy, its nature and modes of transmission. He used the term neural energy without committing himself to any special theory. The rate of transmission of nerve energy in the ameba and lowest forms of animal life in which it was a general diffusion was only about three feet per second, whereas in the higher vertebrates, where it moved along chosen pathways, it reached as high as 150 feet per second. There was an enormous output of energy relative to the small size of the productive sources of supply, as shown by Dr. H. H. Donaldson's contributions. In the adult human brain of 1360 grams the weight of the nerve-cell bodies was less than 27 grams.

There were nine thousand two hundred million nerve-cell bodies in the newborn babe, and the same number in the adult. Two per cent. represented the proportional volume of the cortical cell bodies, including all the dendrons. Many agencies affected the delicate responsive neural conductors and their related centers, those which were most common being related to variations in atmospheric pressure and storm conditions. The next question was that of the chemical changes which accompanied the transmission of neural energy along nerves. These living wires, the nerves, ate, drank, and ejected, and were fed and did work, and therefore must undergo chemical changes through loss and for repair. Certain excitocontractile impulses were found in plants, and these were probably identical with those observed in animals, as was evidenced by observations upon the mimosa. He could well imagine a neurotic crusade against cruelty to plants after watching experiments on the mimosa. The analogue of the irritocontractile muscle of animal life was in the plant cell walls, which, contracting, expelled fluid and thus caused in the leaves mechanical changes of position. Numerous observations and experiments had been made upon plants, especially the mimosa, with a view to determining the analogies between the movements of such plants and those occurring in the living animal. He next directed attention to some facts and theories regarding what he designated the "symptom signals," called reflexes. As regards the reinforcement of reflexes, the researches of Mitchell and Lewis, Bowditch, Howells, and other American contributors to this subject showed that not only the hand grasp and other coarse movements tended to increase the muscle-muscle and the skin-muscle response, but that nearly every distinct sensation increased them. Sudden light or sound, remotely applied heat, abrupt cold, a pinch, the pull on a single hair, added to the response. The explanation of these reinforced phenomena appeared to be that the afflux of energy giving increase of the reflex was due to the liberation of energy far in excess of the functional needs of the active organ—that is, an overflow of energy, as was shown by observations and investigations. Speaking of the practical applications of this study of overflow, was it not conceivable that there were acquired conditions of the body, neurasthenic and hysteric, in which these endless normal overflows might be mischievously felt and might account for suddenly visible symptoms of nervous excitement? An interesting clinical phenomenon which he believed illustrated the subject of overflow was to be seen in the case of violent facial neuralgia, in which to talk, to laugh, to chew, evoked maddening pain. Were we not in such cases in the presence of an example of reinforcement from overflow of related motor centers affecting a sensory ganglion excitably ready to call forth the phenomenon called pain?

A Study of Errors in the Diagnosis of General Paresis.—Dr. E. E. SOUTHARD of Boston read this paper. He said that 247 cases of mental disease had passed through the daily clinics of the Danvers Insane Hospital and later come to autopsy during the years 1904-1908. Sixty-one of these had been diagnosed clinically with more or less certainty as cases of general paresis, and forty-one of the sixty-one as absolutely certain. Thirty-five of the forty-one had been confirmed by autopsy, and two more had appeared at autopsy, although unsuspected during life. These two unsuspected cases and the six erroneously diagnosed cases had been specially studied. Tabes and cerebellar arteriosclerosis, in the presence of mental symptoms, had been shown to be in two main causes of error in the positive diagnosis.

A Critical Study of the Sensory Functions (Especially Stereognosis) of the Pre-Rolandic Area.—Dr. HERMAN HOPPE of Cincinnati read this paper, saying that the object of his paper was to show how often astereognosis occurred in lesions of the motor zone, and whether the loss of stereognosis was in any way distinguishable from the loss of this function due to lesions of the parietal lobe. His first case had been one of loss of stereognostic sense

combined with loss of muscle sense and sense of position. Autopsy had shown a noninfiltrating tumor the size of a hen's egg situated subcortically in the superior parietal convolution. His second case had been one of subcortical solitary tubercle, involving the arm center in the ascending frontal convolution and the neighboring frontal lobe, demonstrated at operation. Prior to operation there had been some astereognosis in the right hand; after operation, which involved the tumor site, astereognosis in the right hand had been marked. His third case had been one of left brachial monoplegia following Jacksonian seizures without any loss of sensation prior to operation. At operation no gross lesion had been found, but, after locating the center for flexion and extension of the hand, this center had been excised. Following operation there had been complete paralysis of the left arm, with complete astereognosis, all other qualities of sensation being intact. The question which arose was whether astereognosis unassociated with loss of tactile and muscle sense would indicate a lesion of the motor zone and astereognosis with loss of tactile sense, muscle sense, and sense of position indicate a lesion of the parietal lobe. This question could not be decided by a study of recorded cases, although his cases seemed to answer in the affirmative.

Dr. Morton Prince of Boston said that the whole question of stereognosis was a matter of fact and not of induction. Dr. Hoppe's cases were extremely interesting, and they opened a new discussion on the subject. If there was a disturbance of muscle or tactile sense it was impossible for any one to determine what an object was. There were a number of cases on record of asymbolia and astereognosis, meaning by asymbolia loss of power to recognize objects where there had been no loss of tactile sense. The important thing was to determine whether or not there was loss of the sense of position, localization, and so on. Very accurate and careful tests must be made, and they must be made by precise methods.

Dr. C. K. Mills of Philadelphia said there were several interesting points in Dr. Hoppe's communication. A number of things in the paper seemed to contradict the views which some others as well as himself held personally. In cases we had to take information on various points before deciding as to their absolute value. The operative cases could not be absolutely depended upon with regard to the exact extent of the absolute section and also with regard to the extent of the influence of that section. We had to take into consideration the physiological reaction along certain anatomical-functional lines. Undoubtedly the motor region was connected by association fibers with the stereognostic region if it existed, and also doubtless with sensory regions in the post central convolution. We had in these cases the abeyance or the loss of such a sense as stereognosis. Very rarely cases existed in which astereognosis existed without impairment of the muscle sense or sense of position. To a certain extent it proved, not that there was no astereognostic center in the parietal lobe, but that by the destruction of entering tracts astereognosis might be produced.

Dr. William G. Spiller of Philadelphia said that Dr. Hoppe had said that these disturbances of stereognosis with pain had been present only for a short time after operation. They had not persisted. Dr. Hoppe had considered the results carefully. We must be careful after operation on the brain in reaching conclusions. Not only was there disturbance of associated areas, but there was also disturbance from handling the brain; there was disturbance in function of that part; and, what was more serious, in excising any portion of a brain it was necessary to tie the veins supplying that portion. As a result of this tying the circulation was disturbed in adjoining areas of the brain, and softening might occur from this, even if no great number of vessels were tied.

Dr. B. Sachs of New York City stated that an experience he had recently had might throw a little light on this subject. A young woman had had the general symptoms of brain tumor with very slight involvement of the upper extremity. Aphasia had been complete and there had been not only asymbolia, but absolute loss of all sense of the muscular movements. In this case the aphasia had been by all means the most pronounced symptom. The paresis had been so slight that except for detailed examination it might have escaped altogether. Basing the location on that fact he had suggested that the surgeon go in over the arm center, but that he keep as far posteriorly as possible. There was found a tumor which extended to the central fissure and invaded a considerable portion of the cortex into the parietal region. Within 24 hours of the time of operation the aphasia had disappeared entirely. The paresis, however, had remained exactly the same as before the operation, and was practically the same to this day.

The Type and Distribution of Sensory Disturbances Following Cerebral Lesions.—Dr. Carl D. Camp of Ann Arbor, Mich., read this paper, stating that dissociation of sensation frequently followed cerebral lesions. The type of dissociation was not constant, but probably depended on the location of the lesion. The disturbances of sensation were usually confined to one side of the body, but some cases apparently showed that there was rerepresentation in the cerebral cortex of the sensory distribution of spinal segments. A case which he had observed showed marked dissociation of sensation and strongly suggested spinal segmental sensory representation in the brain.

Inversion and Interlacing of the Color Fields an Early Symptom of Brain Tumor.—Dr. Harvey Cushing of Baltimore read this paper, saying that the report was a preliminary one and was based upon observations made in conjunction with Dr. James Bordley, Jr. The history of most brain tumors extended over a period of years rather than months. It was, perhaps not, surprising to find that almost every patient brought for operation after the diagnosis of brain tumor had been finally certified by the often long-delayed ophthalmoscopic changes, had at an early stage of the trouble been regarded as hysterical or the subject of some psycho-neurosis. Following Charcot an impression still held sway that more or less contraction of the field for form with partial or complete color reversal (dyschromatopsia) was the great "essential sign of hysteria." These alterations of the visual fields were no less characteristic of brain tumors. We had found no definite relationship between the contraction of the field for form and that of the color field. Some patients had shown the typical hysterical concentric contraction with color reversal, but in many of them there had been a prompt return to the normal relations after a simple decompression. Other cases had shown peripheral limitations greater in fields for form than in color fields, the red being less affected than the blue. There had been other cases in which contraction for colors and form went hand in hand, though the blue was usually much more affected than the red field. The prominent feature of most of the authors' charts was not so much the preservation of the red field as the alteration of the blue. In several instances there had been a total achromatopsia and a more or less definite hemiachromatopsia for blue alone. The process seemed to be one related in some way to increased intracranial tension, the relief of which usually caused an early subsidence of the dyschromatopsia. These visual disturbances did not seem to be dependent upon neuroretinal edema, since in a number of patients they had preceded any appreciable ophthalmoscopic changes.

Exhibition of a Number of Lantern Slides Illustrating Interesting Pathological Conditions.—Dr. M. Allen Starr of New York presented these slides, for which he

was indebted to Dr. Larkin. The first was a section of the spinal cord from a case of anterior poliomyelitis, in which death had occurred on the fifth day of the disease. In this specimen could be seen enormous infiltration of the gray matter and distention of the capillaries. The motor cells of the cord had practically disappeared. The next specimen was a section from the first lumbar level of the spinal cord of anterior poliomyelitis in a child who had died six months after the onset of the disease, and showed bilateral infection of the anterior horns and a remarkable rarefaction of the anterior horns, resembling syringomyelia. The next was a section of multiple sclerosis of the spinal cord, the sclerotic patches being visible here and there and invading, also, the anterior horn of one side. Multiple sclerosis was a rare lesion. In Dr. Starr's clinic he had found but 51 cases of multiple sclerosis in 31,000 consecutive cases. The next specimen was from a patient dying 12 days after the onset of "grippe." There was a condition of acute hemorrhagic infiltration of the cord, with enormous distention of the capillaries everywhere and exudation from the capillaries of red blood corpuscles which were present throughout the entire cord, causing a disintegration. He showed a specimen of the spinal cord from a patient who had died suddenly after coming from a caisson. The rapid change from the atmospheric pressure of four or five atmospheres to the ordinary pressure was accompanied by the evolution of gas in the blood-vessels, and also by apparently the same effect both in the blood and in the tissues generally seen in champagne when it is uncorked; there was a sudden evolution of gas. This was the condition that occurred in this man's spinal cord, practically blowing up his spinal cord and disintegrating it absolutely. The next condition shown he had never seen described in the books or pictured; it had been found by Dr. Larkin a number of times in autopsies of patients who had died in the alcoholic wards of the Bellevue Hospital apparently from alcoholism. There was an infiltration beneath the pia mater of blood in small amounts, without any rupture of any visible blood-vessel. If the pia was picked off no clot was found under it; it was simply infiltrated everywhere with blood. Another case was that of hemorrhage into one of the lateral ventricles. The interesting feature of this case was that no rupture of any blood-vessel could be found; it seemed to have been a gradual infiltration of blood into the ventricle secondary to a condition of leucocythemia. The next was a case of abscess of the temporal lobe subsequent to ear disease, showing that caries of the petrous portion of the temporal bone might give rise to a pretty extensive abscess. The next was an abscess of the frontal lobe of the brain subsequent to operation upon the nose. The next was a rather extensive tumor of the middle lobe of the cerebellum, with a cyst in the center. This had been diagnosticated, but no attempt was made to operate, as the patient's condition did not warrant it. The next specimen confirmed a statement that Dr. Spiller had made not very long ago, to the effect that extensive hemorrhages in the brain might occur without causing sudden death. This was a hemorrhage which involved nearly half of the left hemisphere of the brain, occurring just above the level of the basal ganglion, near to the corpus callosum, and the patient had lived three and one-half days after the onset of the disease. At autopsy cases of gumma as extensive as the one shown were not often found; it covered the whole half of the brain cortex, and could easily have been stripped up and taken off by an operation. It would be difficult to absorb as large a thing as that by mercurial inunctions and iodide of potassium. He saw no reason why in well-marked tumor of the brain in syphilitic individuals, if a very marked improvement was not obtained in the course of two months, it would not be perfectly legitimate to go down and remove a gumma just as would be done with any other tumor of the brain. The next picture was one of an enormous aneurysm of the basilar artery pressing upon the base of the brain and the medulla oblongata, and it would have been supposed that it would have involved some of its nerves. The interesting feature of the case was its history. The patient who had owned that brain had not been the patient of anyone. He had been organist in one of the large churches, 45 years of age, a man who had been known to the vestrymen as being a man in very good health. He had never failed at the rehearsals or services, and last Easter Sunday he had presided at the organ and had given an elaborate musical service. He had come out after the musical service and dropped dead on the street, and had been taken to the Morgue. An enormous aneurysm of the basilar artery had been found, though he had presented absolutely no symptoms during life. The next was a large cystic tumor of the brain, involving the area of the pituitary body, which must have been of embryonal character. The man who owned the tumor was a longshoreman, in perfect health, who had done his work in loading and unloading the White Star steamers. One day he had sat down on the edge of the dock to take his luncheon. His associates had not missed him that afternoon, but two days later he had been found sitting there, and that was what he had had in his head.

Clinical Report of a Case of Sarcoma of the Motor Area of the Left Hemisphere.—Dr. C. Eugene Riggs of St. Paul read this paper, saying that a woman, aged 48, awakened from a sound sleep on the night of December 25, 1906, and found herself unable to speak for about five minutes. She had tonic spasm of the right side of the face, accompanied by a peculiar, unintelligible noise. Afterwards she had spoken of her tongue as feeling thick. There had been four similar seizures in March and one in June, continuing irregularly until October, after which there had been almost complete cessation for months. Troubles in speech had been first noticed in October. Also a poor memory and sluggish mentality. The latter part of March, 1908, there had been first noticed paresis of right hand and arm, which rapidly spread to the entire side; also marked double optic neuritis. The patient had never suffered any pain. An exploratory operation showed an infiltrating mass involving the left motor area, which rendered a radical operation impossible. The mass proved at autopsy to be sarcomatous.

Friday, May 28—Second Day.

Dr. Pearce Bailey of New York City in the Chair.

Mongolian Idiocy.—Dr. William N. Bullard of Boston exhibited a number of *x*-ray plates of cases of Mongolian idiocy to show the condition of the bones and cartilages. The plates included the hand, foot, and head. The principal thing shown in these cases was the remarkable difference in size between the brain of the Mongolian idiot and that of the normal child of the same age. A peculiarity in this class of cases was that the bones and cartilages differed simply in size and very little in structure.

A Case of Subcortical Auditory Aphasia, with Description of the Anatomical Lesion.—Dr. Albert M. Barrett of Ann Arbor, Mich., presented this paper, in which was reported the disturbances of speech in a man who, following an attack of apoplexy, had become unable to understand spoken words, and to repeat mechanically. Reading and writing had been preserved. Spontaneous speech was intact, except for a very slight paraphasia. Post-mortem findings were softening in the right and left first and second temporal convolutions. The lesion was largely subcortical. There was preservation of the cortex of the inner half of the middle part of the left first temporal convolution and the entire root of this convolution.

Distinction Between the Psychoneuroses Not Always Necessary.—Dr. G. L. Walton of Boston read this

paper, saying that much confusion existed regarding the classification of cases presenting nervous symptoms without known organic basis. In well-marked cases there was little difficulty. Such symptoms as aphonia and anesthesia indicated hysteria; flight of ideas and pressure of activity, alternating with retardation of thought and profound depression, were easily recognized as meaning manic-depressive insanity, and so with all well marked cases. But there was a large class of patients showing symptoms which were common to manic-depressive insanity, hysteria, hypochondria, and neurasthenia. Much unnecessary effort was made to place each of these cases under one or the other category. The textbooks attempted without success to make clear the distinction between mild forms of these disorders. It should suffice to class these mild cases simply under the term psychoneurosis, unless definite symptoms developed. Nothing was lost by including under this term most of the cases classed under neurasthenia, a misleading term, since it implied an asthenic condition not always present, whereas "psychoneurosis" indicated the essential state of all patients now included under neurasthenia.

Dr. Adolf Meyer of New York demonstrated a number of illuminated glass reconstructions of brains and discussed a case of transcortical sensory aphasia with integrity of the transverse temporal gyrus and of the auditory radiations, and a case of complete word-deafness with destruction of these parts.

The Organic Basis of Emotional Expression Illustrated by Cases of Involuntary Laughing and Weeping.—Dr. Charles K. Mills of Philadelphia read this paper, saying that the main object of his paper was to demonstrate the probable cerebral mechanism of emotional expression, or, in other words, to prove the existence in one of the basal ganglia of a reflex, emotive or mimetic centre related by connecting tracts to both exciting and inhibiting emotive centres in the cerebral cortex, and by emissive tracts to the centres for facial expression in the bulb, and to spinal centres for movements of the limbs concerned with the expression of emotion. He referred to a series of cases, some without and some with necropsy, to illustrate the arguments advanced. He exhibited photographs illustrating various phases of the subject, as the appearance of pain and anguish in the face, and the facial contortions in cases of involuntary weeping and howling; the expression in a case in which, because of bilateral lesions, the patient's expression was that of a perpetual grin; and a case in which the ability of the patient to contract the muscles on either side of the face voluntarily was present, while only the left side was set in motion in the act of laughing. Some of the conclusions which he believed to be warranted by the study of these cases were: (1) In the thalamus or lenticula, or in some undetermined region at the base of the brain, a center for mimetic expression was located, although von Bechterew's view as to the thalamic center could not be regarded as absolutely demonstrated; (2) This center was connected with a prefrontal cortical evoking center, and also with an inhibitory motor center; (3) The pathway from the prefrontal center was probably by way of the anterior limb of the internal capsule and one of the segments of the lenticula; (4) The pathway for the motor inhibitory center was probably by way of a tract at or near the knee of the capsule; (5) The emissive tract from the basal emotive center to the nuclei of the bulb and spinal cord was probably independent of the pyramidal tracts, although passing in close contiguity with this tract; (6) The cortical centers, evoking and inhibitory, concerned with emotional expression were more highly developed in the right cerebral hemisphere than in the left, in this way contrasting with the speech centres with their high development in the left hemicerebrum.

Dr. Morton Prince of Boston stated that attempts had been made by psychologists and neurologists to solve this problem, but it was so large and had so many aspects that it was a very difficult one. Recently Roussi had undertaken to reinvestigate this whole problem and, if his experiments stood, the optic thalamus would have to be eliminated as a center.

Dr. M. Allen Starr of New York said he hoped that in the review of the literature Dr. Mills would give due credit to Dr. Seguin, who had published a paper which had been reprinted in his Opera Minora, and which contained almost every fact that Dr. Mills had presented. Clinically he divided cases of disturbances of emotional expression into (1) the cases to which Dr. Seguin had called especial attention, of emotional disturbances connected with the pons Varolii, with or without involvement of the optic thalamus; and (2) the cases that showed emotional disturbance where the lesion was above the level of the crus where we had distinct hemiplegia, usually transient and leaving a lack of emotional control.

Dr. Ernest Sachs of New York said that during the past year and a half he had been engaged on some experimental work on the thalamus in the laboratory of Sir Victor Horsley and some of this work might throw light on the question Dr. Mills had raised. There was evidently a distinct connection between the thalamus and the cortical facial center, for a lesion in the lower part of the lateral nucleus of the thalamus led to degenerations which go exclusively to the facial center, while the region dorsal to this sent fibers to the arm and leg centers. Furthermore, his work had shown that only the lateral part of the thalamus, that portion outside of the lamina interna, was connected with the cortex. The median and anterior nuclei were only connected with the caudate nucleus. The center median seemed to be only an association center among the thalamic nuclei, and gave origin to some of the fibers of the posterior longitudinal bundle. The hypothalamus was not intimately connected with the thalamus, as heretofore supposed, but bore a much closer relation to the globus pallidus of the lenticular nucleus. As to the functions of the thalamus, much still had to be done, but certain points already seemed to be disproved. There was no evidence of any lachrymation arising from thalamic stimulation, as the Russians under v. Bechterew had claimed. Screaming, when it did occur, was pronounced only when the termination of the fillet fibers were irritated, and this should probably be interpreted as meaning that the current had produced a strong sensory impulse in response to which the animal screamed. The motor phenomena in the median part of the thalamus were mainly concerned with movements of the eyes usually conjugate in type, and this might be a superior peduncle response.

Dr. James J. Putnam of Boston had seen the bulbar patients act in the manner described by Dr. Starr, yet with no particular emotion. There was a fairly close resemblance in some stages between the movements which went with pleasure and those which went with grief, and one seemed to be an intensification of the other.

Dr. Hugh T. Patrick of Chicago said this group of symptoms was more apt to occur in bilateral or multiple lesions. One of the principal elements was probably a lack of inhibition.

Dr. Charles L. Dana of New York said that he had studied lately the syndrome of optic thalamus lesions, and that we knew now quite definitely what happened in ordinary optic thalamus lesion. It seemed to him that the old idea that the thalamus had something to do with expression was not correct, and certainly not unless the thalamus was injured on both sides. Acute lesions of the pons were associated with explosive laughter and crying. In his experience, the location of the lesion when there was an explosion of laughter or crying had been almost always in the lenticular zone. The disturbance was often associated with disturbance of speech, as certain forms of jargon aphasia.

So far as clinical and pathological investigations went, we had to point to the lenticular zone and pons as being the places which were anatomically localized as the most important seats for the mechanism of expression.

Dr. C. K. Mills said that he had already in his notes given full recognition and consideration to the writings of Seguin and Roussi. His own views were that the part the mechanism had in evoking the control of emotion was a complicated one; that a center, concentrated part of the neural mechanism, did reside at the base of the brain. He was not sure that it was in the thalamus. He was inclined to think that it was in the lenticular zone.

A Contribution to Our Knowledge of the Idiopathic Otalgias and Their Surgical Treatment: Tic Douloureux of the Facial Nerve with Cure by Physiological Extirpation of the Geniculate Ganglion.—Dr. L. Pierce Clark and Dr. Alfred S. Taylor of New York presented this communication. Dr. Clark said that it had been fairly well proved that the facial was a mixed nerve, that its sensory ganglion was the geniculate ganglion and its sensory root the pars intermedia of Wrisberg. This ganglion was of the spinal type and, therefore, eligible to inflammations, as, herpes zoster, and degenerations, as, tic douloureux. It was probable that not a few neuralgic conditions of the ear were derived from disease of the sensory part of the facialis and not, as commonly supposed, of reflex origin from the teeth, nose or throat. The neuralgic area of the facial as concerns otalgia was the anterior wall of the external auditory canal and the skin just in front of the ear. This was also supplied by a branch of the trifacial, but if all other parts of the trifacial were unaffected pain in this area doubtless had its seat in the facial. When all other antineuralgic measures had been exhausted without relief it was logical to assume that, as in trifacial neuralgia, operation should be done, consisting in case of the facial of physiological extirpation of the geniculate ganglion by cutting the pars intermedia. A patient of his, Mrs. E. L., aged 28, had begun in February, 1907, to have stabbing pain just in front of the left ear, which later became of daily occurrence and lasted two to three hours. Ear, eye, throat, and general medical examination had given negative results, hence the conclusion had been reached that the pain was a true tic douloureux of the geniculate system and physiological extirpation of the geniculate ganglion had been recommended. This had been performed by Dr. Alfred S. Taylor, whose report follows.

Dr. Taylor said that the patient had been referred to him by Dr. Clark, with the request that the geniculate ganglion be removed, but researches on the cadaver had shown this to be impracticable on account of the danger of doing injury to surrounding structures; therefore, it was decided to cut the sensory root in the posterior fossa of the skull. An osteoplastic flap was turned down in the occipital region, the dura incised with the base of the flap toward the midline and its upper border just below the lateral sinus; the cerebellum was retracted and the pars intermedia exposed at the internal auditory meatus, and the seventh nerve and the upper part of the eighth nerve cut. The result was a complete facial palsy and deafness of the left ear, but the patient had complete relief of pain. The facial palsy was slowly improving and hearing had been completely restored.

The Reflexes in Hysteria.—Dr. Philip Coombs Knapp of Boston said that Babinski had claimed that hysteria was incapable of modifying the tendon reflexes, and some of his followers had also contended that the skin reflexes were not altered. This was contrary to the old teaching that the skin reflexes were diminished over the anesthetic area, and that the tendon reflexes were often exaggerated on the paralyzed side in hysterical hemiplegia. He had studied the reflexes in 100 cases of hysteria in which there had been a diminution of sensibility on one side of the body. He took exceptions to Babinski's claim that such a hemianesthesia was due to unconscious suggestion by the physician. He had found some exaggeration of the tendon reflexes in 86 cases and considerable exaggeration in 41; a greater percentage than was found in normal persons. He felt very skeptical as to the existence of true ankle clonus, loss of knee-jerk or Babinski's reflex due to hysteria. The reflexes had been found to differ on the two sides in 76 cases. In 57 cases the tendon reflexes had differed on the two sides, the knee-jerk differing in 37 and the ankle-jerk in 30. In 38 cases the tendon reflex had been greater on the anesthetic side, in 19 on the sound side. The plantar reflex had been absent in only 2 cases out of 24, and the abdominal reflex had been diminished or lost in the anesthetic side in 24 cases out of 51. These cases, therefore, showed that hysteria apparently modified both the skin and tendon reflexes.

Primary Degeneration of the Pons, Cerebral Peduncles, Medulla, and to a Less Extent of the Cerebellum, Associated with Primary Degeneration of the Cortico-Spinal Tracts; with Autopsy.—Dr. T. H. Weisenburg and Dr. S. D. Ingham of Philadelphia presented this paper. Dr. Weisenburg, reading, said that a man of 42, with an unimportant family history, had developed a tremor of his entire body, with staggering and uncertain gait, headache, and dizziness, followed by increasing weakness and spasticity of the lower and then the upper limbs, and a gradual difficulty in talking, eating, and swallowing, with involuntary laughing and crying. There had been weakness of the tongue, palate, and facial muscles, but no fibrillary tremors or atrophy. Ataxic movements of the eyeballs had been present early. The reflexes had been everywhere increased with bilateral Babinski. The autopsy had shown a primary degeneration of the pons, cerebral peduncles, medulla, and cerebellum. There had been, besides, a primary degeneration of the cortico-spinal motor fibers.

Thrombosis of the Cervical Anterior Median Spinal Artery; Syphilitic Acute Anterior Poliomyelitis.—Dr. William G. Spiller of Philadelphia presented this paper and said that, with the exception of the case reported in this paper, he knew of no instance in which thrombosis had been demonstrated by necropsy to be confined to a small portion of the anterior cervical supply. The case was a contribution to syphilis as a cause of acute anterior poliomyelitis; to the position of the fibers of pain and temperature in the anterior part of the lateral columns and of the fibers of tactile sensation in the posterior columns; and to the pathology of brachial paraplegia. It demonstrated that occlusion of a limited portion of the anterior arterial system of the spinal cord or medulla oblongata produced a symptom-complex that should be capable of diagnosis even without necropsy. The case was as follows: About four years previous to his paralysis the patient had what was supposed to be spinal meningitis, from which he had recovered. He had been in excellent health, and was employed at the time the paralysis occurred in an ice house, and with another man had been lifting blocks of ice weighing about 100 pounds. Fifteen or twenty minutes after lifting the last block he had begun to have pain between the shoulders, and felt numb and weak in the upper extremities. Ten or fifteen minutes later he had felt weak and numb in the lower limbs. He had gradually recovered the use of the lower limbs, although they had remained somewhat spastic. He had normal sensation of touch everywhere. Sensations of pain and temperature had been much affected in the lower and upper limbs, and these limbs had been much wasted. The microscopic examination had shown that the lesion was thrombosis. The whole anterior part of the cord, from the fourth cervical to the first thoracic segment, inclusive, had been much degenerated. The pyramidal tracts had been only slightly

affected. The lesion affected the blood supply of the anterior part of the cord. The thrombosis had probably been syphilitic in origin.

Pathogenesis of Tabetic Arthropathies Based Upon the Anatomical and Histological Study of Two Cases.—Dr. Alfred Gordon of Philadelphia read this paper, saying that a degenerative state of the peripheral nerves was an essential element in the causation of the arthropathy, yet another factor was necessary, and this was trauma. In view of the hypotonia, loss of tendon reflexes, and loss of sensations, traumata of the joints might occur very readily and pass unnoticed. In two of his cases slight traumata had become the starting points for later arthropathies. The smallest nerve branches distributed within and around the affected articulations (knees and foot), also the blood vessels had been carefully examined microscopically. Identical nerve branches and blood-vessels had been taken from the unaffected side of the body and equally examined for the purpose of control. Degenerative conditions were found in the nerves on both sides; very slight changes were found in the blood-vessels. The conclusion was that, while degeneration of peripheral nerves was a *sine qua non* in the genesis of tabetic arthropathies, trauma was an indispensable element.

Saturday, May 29—Third Day.

Dr. F. W. Langdon, Second Vice-President, in the Chair.

Pain in Tabes Dorsalis an Important Differential Diagnostic Point from General Paresis.—Dr. E. D. Fisher of New York read this paper, saying that the pains of tabes were lightninglike and distributed in the peripheral nerves either in the upper or lower extremity; girdle or bandlike, and of a duller character either in the lumbar or dorsal region; or in the form of the paroxysmal crises of pain involving the various visceral organs, as the stomach, bladder, heart, etc. These pains in typical cases of general paresis were rare, though we had general paresis of the tabetic type; that is, with irregular spinal symptoms in which pain was present. He drew attention to this one symptom to emphasize his opinion that we had two distinct diseases in general paresis and tabes dorsalis.

The Surgical Treatment of Athetosis and Spasticities by Muscle Group Isolation.—This paper was prepared by Dr. Sidney I. Schwab and Dr. Nathaniel Allison, St. Louis, and presented by Dr. Schwab. Athetoid and spastic conditions of organic origin were essentially similar processes due to several factors; the essential mechanism was nervous in origin. The term "muscle group isolation" implied the isolation of the muscle or group of muscles at fault in the production of contracture deformity or athetosis. It was made effective by cutting off from the central nervous system the connection along which the abnormal impulses, active in causing spasticity or athetosis, were transmitted. This was done by isolating the nerve and injecting it with an alcoholic solution. There resulted an immediate paralysis of the physiologically stronger group of muscles, without interfering with the free muscular use of the antagonists. At this point physiological exercises, planned to strengthen further the antagonists, might be used.

Dr. B. Onuf of New York said he had observed that athetosis was essentially a symptom of diseases which had been acquired at a very early age. He had not seen a single case of athetosis in which the lesion which caused it had been acquired in adult life. He explained this to himself theoretically by assuming that there was an interruption in the pathways between the cortex and lower centers at an early date, and then these lower centers acquired a certain independence, and movements were acquired which were entirely independent of the will. If this was the case, then, if the offensive muscles were paralyzed for a period of six months, these lower centers might again forget and the cortical centers again gain their ascendancy.

Dr. Schwab said that in case of athetosis we not only paralyzed the muscles, but their sensory supply totally, because there was a theory that athetosis also depended upon the abnormal sensory impulse as well.

Hereditary Spastic Paraphlegia, with Report of Seven Cases.—Dr. John Punton of Kansas City, Mo., read this paper, saying that hereditary spastic paraplegia was comparatively rare. In the seven cases he reported heredity had been the chief etiological factor and had been of great diagnostic and prognostic value. The first group consisted of four cases, viz., the mother, aged 59, in whom the disease had had its onset after her marriage at the age of 23; a son, aged 34, in whom it had its beginning at 16; a son, aged 32, in whom it had begun at 15; a son, aged 24, in whom it had begun at 14 or 15. The second group consisted of three cases, viz., the mother, aged 43, in whom the disease had begun at 33; a daughter, aged 7 years, in whom it had begun at six years; a daughter, aged 5 years, in whom it had begun in infancy. As the disease was incurable, the only measures to be taken were prophylactic and consisted in discouraging marriage in persons with a tendency toward this disease.

Occupation Neuritis of the Thenar Branch of the Median Nerve; a Well-Defined Type of Occupation Atrophy of the Hand.—Dr. J. Ramsay Hunt of New York read this paper and said that a well-defined clinical type of atrophy of the hand resulted from an occupation neuritis of the thenar branch of the median nerve, which was induced by a compression of small motor branch of the median nerve, as it emerged from beneath the anterior annular ligament of the wrist. This thenar branch was purely motor, and innervated the abductor pollicis, opponens pollicis, and the outer head of the flexor brevis pollicis. This group of cases was characterized clinically by a sharply defined atrophy, confined to the distribution of this nerve. The thenar eminence presented a "scooped-out" depression, lying between the outer border of the first metacarpal bone and the inner head of the flexor brevis pollicis. There were present well-marked reactions of degeneration in the affected muscles, and objective sensory disturbances in the distribution of the median nerve were absent. This type of atrophy interfered very little with the usefulness of the hand, as all the other muscle groups were normal. He also called attention to another well-defined type of occupation atrophy of the hand, described by him, which was dependent upon an occupation neuritis of the deep palmar branch of the ulnar nerve as it passed between the tendinous origins of the abductor minimi digiti, and the flexor brevis minimi digiti. In this type all the intrinsic muscles of the hand were paralyzed, with the exception of those which are supplied by the median nerve, and here, as in the thenar type of occupation atrophy, sensory disturbances were entirely absent, the deep palmar branch of the ulnar being a purely motor nerve. The importance of these two types of occupation (motor) neuritis became immediately apparent from the resemblance which they bore to the Aran-Duchenne type of spinal atrophy. This resemblance was enhanced by the well-known fact that progressive muscular atrophy, beginning in the small muscles of the hand, not infrequently developed with occupations necessitating an over-activity of these members. There was no question but that cases which belonged to one or the other of these two groups of occupation atrophies without sensory disturbances were not infrequently erroneously diagnosed as spinal atrophies. Hence their clinical and diagnostic importance.

Horizontal Oscillation of the Eyeball in Paralysis of the Orbicular Branches of the Facial Nerve.—Dr. L. Pierce Clark and Dr. H. H. Tyson of New York presented this paper, saying that it was fairly well known

that in Bell's palsy the upward and inward or outward rotation of the eyeball was a physiological act, and was not pathognomonic of any special type of palsy, as it might be shown in a normal person. Schlesinger had reported one case of horizontal oscillation and a few other observers had noted the same phenomenon. It consisted of a see-saw oscillatory movement of 40 to 60 vibrations a minute when a persistent, forceful attempt was made to close the lids, the opposite eye participating in the movement. They reported three cases. The explanation was as difficult as that for ordinary nystagmus.

How Should the Paroccipital Fissure Be Represented in Fissural Diagrams?—Dr. BURT G. WILDER of Ithaca, N. Y., presented this paper, saying that commonly this and the parietal fissure were interpreted and represented as, respectively, the occipital and horizontal components of the intraparietal fissural complex. In apes and monkeys, young and adult, they were always; the fetal conditions were unknown. In the human fetus they always commenced independently and remained separate in about 40 per cent. of hemicerebrums, but united sooner or later in the other 60. In many, perhaps most, of the cases of superficial continuity the original isthmus might be recognized as a more or less deeply submerged vadum or shallow, and it was a fair question whether cases in which the fissure at this point was less than one-half the greatest depth at either side should not be regarded as cases of separation rather than continuity. Superficial continuity was two or three times as common as separation on the left side, but on the right separation was more common, about 55 per cent. In the light of existing knowledge, the writer concluded that fissural diagrams should include the dorsocaudal aspect of this region, with continuity of the two fissures on the left and separation on the right; when only one lateral aspect was shown the fissures should still be separate, but there should be a statement as to the conditions in the lower primates and in the human fetus and average adult.

The Herpes Zoster Oticus: A Study of the Zoster Zones of the Geniculate Ganglion of the Facial and the Jugular Ganglion of the Vagus.—Dr. J. RAMSAY HUNT of New York presented this paper, in which he called attention to the herpetic inflammations of the geniculate ganglion of the facial nerve, a syndrome described by him before the association three years ago. The present study was an attempt to define more accurately the zones of the geniculate area and to differentiate the geniculate zone from the zones of the glossopharyngeal and the jugular ganglion. Three kinds of evidence were considered: anatomical, embryological, and clinical. The latter was based on the analysis of twenty-five cases of isolated herpes oticus, which included six personal observations. In consideration of this evidence, he believed that the geniculate area was represented on the following anatomical landmarks of the ear: The external meatus, concha, tragus, antitragus, antihelix, fossa of the antihelix and the external surface of the lobule; that the zones for the jugular ganglion of the vagus and the petrous ganglion of the glossopharyngeal were represented on the posterior portion of the tympanic membrane, and the posterior wall of the auditory canal, as well as a cutaneous strip on the posteromesial surface of the auricle and the adjacent mastoid region. The other portions of the auricle, anteriorly and posteriorly, corresponded to the Gasserian and cervical zones, respectively. Attention was also called to the occasional occurrence of an eruption on the anterior two-thirds of the tongue and soft palate in cases of facial palsy. It was very probable that the facial nerve had a vestigial sensory innervation within the buccal cavity in these distributions, and it was quite possible that such cases were to be explained by herpetic lesions in the geniculate ganglion, although a neuritic origin for this distribution could not be entirely excluded. It was especially emphasized that this attempt to differentiate the zones of the auricle was entirely a preliminary one, and that at the present time, with the material at hand, it was quite impossible to do more than to indicate their probable areas. The clinical importance of herpes zoster oticus was indicated, and the significance of the "zoster" method in determining the zoster zones of the seventh, ninth, and tenth nerves in the auricle. Attention was also directed to the facial palsy and auditory disturbances which so frequently accompanied herpes oticus; also the possibility of pneumogastric disturbances which so frequently accompanied herpes oticus; also, the possibility of pneumogastric disturbances in this group of cases. He also believed that the ganglia of the auditory nerve, the ganglion of Scarpa, and the ganglion spirale, might be primarily involved in zoster symptoms of Ménière's disease.

Dreams as a Diagnostic and Therapeutic Aid.—Dr. B. ONUF of New York read this paper and stated that aid might be obtained from the study of the amalgamation, or mixture, of two or more different characters into one which occurred in a dream; also by noting the reversal of roles played by different characters of real life in dreams. Assistance in treatment of certain conditions might be secured by suggesting a dream to take place in a hypnotic or post-hypnotic condition. For example, in case of a woman who had had an aversion to beans and sweet cabbage, which appeared to be purely psychic, it had been suggested that she dream in a hypnotic state that she was eating these articles with great relish. The result was temporarily what was desired.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June 15, 16, and 17, 1909.

ANATOMY.

Answer any ten questions, but no more.

1. What change takes place in the vascular system at birth?
2. Describe the structure of the arteries and give their nerve and blood supply.
3. How are the saphenous veins formed and where do they empty?
4. Give blood and nerve supply of the tonsils.
5. Describe the renal blood circulation.
6. Describe the sphincter ani externus.
7. How may the fissures of the Sylvius and Rolando be approximately mapped out on the surface of the skull?
8. What would be the collateral circulation if the brachial artery were ligated *below* its profunda branches?
9. Describe the dura mater, and mention the processes and sinuses of it.
10. What nerves form the pharyngeal plexus?
11. Give origin, course, and distribution of the nerves of the palm of the hand.
12. Mention a muscle which moves (*a*) the thumb outward, (*b*) the head forward, (*c*) the foot inward.
13. Give origin, insertion, blood and nerve supply, and action of any one of the following muscles: Gracilis, pectoralis major, semimembranosus.
14. Give a general idea of the internal structure of the cerebrum.
15. Outline on the chest wall (*a*) the lungs, (*b*) the vena cava superior, (*c*) the arch of the aorta, (*d*) the left pulmonary artery.

PHYSIOLOGY.

Answer any ten questions in this paper, but no more.

1. Name the uses of the bile.
2. Name the circulating fluids of the body, and state the functions of each.
3. Define tidal and residual air, and state their normal quantity.
4. Define hemoglobin: state its functions and where it is found.

5. What effect does diet have upon the secretion and quantity of milk?
6. State the functions of the thyroid body and the effects of its removal.
7. Why does blood coagulate? Does lymph coagulate, and, if so, why? What chemical change is essential in either case?
8. Where is the respiratory center? What nerves are given off from it? What does each do?
9. State in order of importance the tissues in which animal heat is generated and by which it is given off.
10. Which of the following are secretions and which are excretions? Aqueous humor, tears, bile, cerebrospinal fluid, urine, perspiration, prostatic fluid.
11. State the immediate and remote effect of cutting the sciatic nerve.
12. State the causes of bodily fatigue.
13. What is a superficial reflex? What is a deep reflex? Name four examples of each.
14. Why does heat prostration occur more readily in a humid atmosphere than in a dry one?
15. State functions of the anterior and posterior spinal nerves. How many pairs are there?

MATERIA MEDICA AND THERAPEUTICS.

Answer any ten questions, but no more.

1. Name (*a*) the officinal preparations of aconite, (*b*) adult dose of each, (*c*) medicinal uses, and (*d*) therapeutic effects.
2. State (*a*) the indications for the use of strychnine, (*b*) dosage for adults, and (*c*) symptoms and treatment of poisoning.
3. What purgatives act (*a*) on the small intestines, (*b*) on the large intestines, and (*c*) dosage of each?
4. (*a*) Enumerate the arsenical preparations used in medicine; (*b*) state their therapeutic properties with adult dose of each.
5. Write a prescription based upon a diagnosis of acute ptomain poisoning.
6. (*a*) Explain the difference between galvanic and faradic current; (*b*) mention the classes of cases for the employment of each.
7. Specify the effect on the arterial system of (*a*) nitroglycerin, (*b*) aconite, (*c*) digitalis, (*d*) veratrum viride, and (*e*) strophanthus.
8. Describe (*a*) the Widal serum test and (*b*) state its value and purpose in diagnosis.
9. Compare (*a*) the physiological action and (*b*) the dosage of podophyllin, cascara sagrada, and aloin.
10. Discuss the therapeutic uses and effects of (*a*) acetanilid, (*b*) heroin, and (*c*) terebene; give dosage of each.
11. Specify (*a*) the method and (*b*) the effects of administering oxygen in pneumonia.
12. Differentiate the symptoms of poisoning by morphine, carbolic acid, and arsenic.
13. Give (*a*) the source, (*b*) therapeutic effect, and (*c*) dosage of pilocarpine.
14. Mention (*a*) three vegetable and (*b*) three mineral astringents with therapeutic employment and adult dose of each.
15. Discuss calomel in respect to (*a*) source, (*b*) effects, (*c*) dosage, and (*d*) incompatibilities.

CHEMISTRY.

Answer any ten questions, but no more.

1. Give the composition and properties of urea.
2. Mention the chemical reason for using lithia and its salts in cases of uric-acid diathesis.
3. What is the normal composition of urinary calculi?
4. Define fermentation, putrefaction, decay.
5. Mention the chemical name for white arsenic, properties and uses.
6. Explain the atomic theory.
7. What is the chemical composition of bone?
8. Name the principal pigment of normal urine.
9. What may very high or very low specific gravity of urine indicate?
10. Give the chemistry of respiration, showing what is inhaled, what is exhaled, and how the gases enter and leave the blood.
11. Define specific gravity.
12. What are the properties of bile? Give the chief constituent.
13. Explain the meaning of the terms reaction and reagent.
14. Give Marsh's test.
15. What is the difference between vegetable and animal life from the chemical standpoint?

HISTOLOGY, BACTERIOLOGY, AND PATHOLOGY.

Answer only ten questions, and not less than three on each branch.

Histology.

1. Name the varieties of muscle, and what are the differences between them?
2. Describe the general characteristics of epithelium.
3. Describe non-medullated nerve-fibers and tell where they occur.
4. How do veins differ from arteries?

Bacteriology.

5. State briefly a method of obtaining a pure culture.
6. Describe a process by which bacteria multiply.
7. Give Koch's rules in regard to the bacterial cause of disease.
8. Why does the air contain more bacteria in Summer than the air in Winter?
9. Differentiate between the bacillus coli communis and the bacillus of typhoid fever.
10. Define immunity; susceptibility.

Pathology.

11. Describe the lesions of the kidney cortex in acute diffuse nephritis.
12. Describe the microscopic appearances of the tissues affected in tuberculous pleuritis.
13. What are the lesions in infantile scurvy?
14. Give the pathology of chronic interstitial hepatitis.
15. Give the pathology of gastric ulcer.

PRACTICE OF MEDICINE.

Answer any ten questions, but no more.

1. Describe autointoxication.
2. Describe ulcerative keratitis.
3. Describe a case of cholelithiasis.
4. Differentiate melancholia and dementia.
5. Describe Widal's serum test and its value.
6. Describe a case of cerebrospinal meningitis.
7. Describe a case of incipient tuberculosis of the lung.
8. How does paralysis of the third nerve effect the eye?
9. Describe (1) functional and (2) organic heart murmurs.
10. Describe râles and give the location and significance of each.
11. Describe renal casts and give the location and significance of each.
12. Describe, (1) vesicular and (2) bronchial breathing, and in what condition does the latter replace the former?
13. Describe, step by step, an uncomplicated case of lobar pneumonitis terminating in recovery.
14. Describe the eruption of (1) measles, (2) scarlet fever, (3) smallpox, (4) chickenpox, and (5) typhoid fever.
15. Differentiate the coma of (1) opium poisoning, (2) alcoholism, and (3) compression of the brain from fracture of the skull.

SURGERY.

Answer any ten questions, but no more.

1. How would you treat fracture of the internal condyle of the humerus?
2. Give indications for inguinal colostomy. Describe the operation.
3. Accidents of anesthesia? How guarded against? How treated?
4. Diagnosis and treatment of varicocele.
5. Give diagnosis and treatment of empyema.
6. Diagnosis of cancer of the stomach.
7. Define volvulus; give treatment.
8. Describe how you would close the abdomen after median section.
9. Symptoms and treatment of dislocation of the semilunar cartilages of the knee-joint.
10. Diagnosis of renal tuberculosis.
11. Discuss septicemia.
12. Give treatment of ophthalmia neonatorum.
13. Give causes, symptoms, and treatment of mastoiditis.
14. Describe technique of operation for carcinoma of the breast.
15. Treatment of syphilis.

OBSTETRICS AND GYNECOLOGY.

Answer any ten questions, but no more.

1. Describe pelvimetry, its uses, and name five of the most important measurements.
2. Tell the method of diagnosing (*a*) ordinary pregnancy, (*b*) multiple pregnancy, (*c*) ectopic pregnancy.
3. Name the various uses to which the tampon may be

put in obstetrical practice and the kind and method of use in the several conditions for which you advise it.

4. Describe the third stage of labor, the dangers which attend it and outline your method of conducting it.

5. Describe the urinary changes during pregnancy.

6. Through what agencies may puerperal infection occur?

7. Describe the principal varieties of puerperal infection and briefly outline laceration.

8. Describe the operation for immediate repair of a complete perineal laceration.

9. Describe three operative measures for the relief of prolapsus uteri.

10. Describe uterine curettage and name three conditions which call for it.

11. Describe the operation for (*a*) ventral suspension of the uterus, (*b*) ventral fixation.

12. What is the Alexander operation and the reasons for or against it?

13. Name the different types of uterine hemorrhage and their causes.

14. Outline treatment for any one type of uterine hemorrhage.

15. What causes pyosalpinix, and what is the proper treatment?

HYGIENE AND MEDICAL JURISPRUDENCE.

Answer any ten questions, but no more.

1. Define disinfectants, deodorants, and germicides. What disinfectants are efficient where spores are found?

2. How do you calculate the annual birth and death rate of a given community? Give illustration, *e.g.:* Last year there were 1,324 deaths and 1,075 births in Trenton, having a population of 90,000; give rate there.

3. Give Pettenkofer's method of determining the percentage of carbon dioxide in the air.

4. What do you mean by hard water? Give tests for relative hardness of water.

5. Describe good milk; give test for same. What sophistications and adulterations are usual?

6. Name the usual quarantinable disease and requirements for each at quarantine.

7. Give directions for making cultures in suspected cases of diphtheria.

8. (*a*) Describe hygiene and sanitary science.
(*b*) Subdivisions of hygiene.
(*c*) Development of hygiene.
(*d*) Uses of hygiene to the public.

9. Describe and give uses of the barometer, thermometer, hygrometer, psychrometer, and anemometer.

10. Give influence of humidity, wind, clouds, and climate upon the health.

11. Define the duties of a school physician.

12. How would you proceed to prevent or overcome malaria in any district?

13. Give different systems of house heating, with advantages and disadvantages of each.

14. Describe potable water; give natural sources and varieties of water with characteristics of each.

15. What impurities are found in water? What are their effects upon the animal economy?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

June 15, 16, and 17, 1909.

ANATOMY.

1. *The changes which take place in the vascular system at birth:* The hypogastric arteries become obliterated; the foramen ovale closes; the Eustachian valves atrophy; the ductus arteriosus and ductus venosus atrophy and become impervious; umbilical vein becomes obliterated.

2. Nerve supply of arteries: Nervi vasorum.
Blood supply of arteries: Vasa vasorum.

3. The SAPHENOUS VEINS are formed from the dorsal venous arch.

The *internal saphenous* begins at the inner end of this arch, on the inner side of the foot; it passes upward in front of the internal malleolus, then upward and backward with the internal saphenous nerve, behind the internal condyle of the femur, then upward and outward to the inner side of front of thigh, through the saphenous opening, to empty into the femoral vein.

The *external saphenous* begins at the outer end of the arch, on the outer side of the foot; it passes upward behind the external malleolus, up along the outer side of the tendo Achillis, with external saphenous nerve, to the popliteal space, where it enters the popliteal vein.

4. TONSILS. *Blood supply:* Ascending palatine, tonsillar, ascending pharyngeal, descending palatine, and dorsalis linguæ arteries.

Nerves: Tonsillar plexus, formed from glossopharyngeal and pharyngeal plexus.

7. To locate the *fissure of Sylvius*, draw a line from a point one and a quarter inches behind the external angular process of the frontal bone and the same distance above the zygoma, to a point three-quarters of an inch below the most prominent part of the parietal eminence. (a) The main fissure will correspond to the first three-fourths of an inch along this line; (b) the horizontal limb will correspond to the rest of this line; (c) the ascending limb will correspond to a line one inch long, going upward (parallel to the coronal suture) from the junction of (a) and (b).

Draw a straight line over the top of the scalp from the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the *fissure of Rolando.*

8. If the brachial artery is ligated below its profunda branches, the collateral circulation is carried on by the branches of the superior and inferior profunda arteries anastomosing with the recurrent branches of the radial, ulnar, and interosseous arteries.

9. DURA MATER. *Processes:* Falx cerebri, falx cerebelli, tentorium cerebelli, and diaphragma sellæ.

Sinuses: Superior longitudinal, inferior longitudinal, straight, lateral, occipital, cavernous, circular, transverse, superior petrosal, inferior petrosal.

10. The *pharyngeal plexus* is formed by filaments from the pharyngeal branches of the glossopharyngeal, pharyngeal branches of pneumogastric and sympathetic nerves.

12. (*a*) Extensor ossis metacarpi pollicis; (*b*) Rectus capitis anticus major; (*c*) Tibialis anticus and posticus acting together.

PHYSIOLOGY.

1. The uses of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

2. The circulating fluids of the body are blood and lymph.

The *functions of the blood as a whole* are: To distribute nourishment, oxygen, and the internal secretions to the tissues of the body; to remove carbon dioxide and other waste matters from the tissues so that they may be excreted by the lungs, kidneys, and skin; to regulate the body temperature. In addition, the *white corpuscles* serve as a protection to the body from the incursions of pathogenic microorganisms; they take some part in the process of the coagulation of the blood; they aid in the absorption of fats and peptones from the intestine, and they help to maintain the proper proteid content of the blood plasma.

The *functions of the lymph* are: To provide the tissues with material necessary to their functional activity, growth, and repair; to receive from the tissues their waste products, and to convey the products of digestion and absorption to the blood current.

3. *Tidal air* is the air which is constantly passing in and out of the lungs during ordinary calm respiration. It measures about 30 cubic inches.

Residual air is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

4. *Hemoglobin* is the coloring matter of the blood; it is found in the red corpuscles; it is crystalline, reddish in color, very complex, and contains iron. Its function is to carrry oxygen from the lungs to the tissues of the body.

5. Too little food decreases both the quantity of milk and the percentage of solids. An ample diet increases both the quantity of milk and the percentage of solids. Abundance of proteids in the food increases the fat in the milk; so also does fat in the food, if it is well digested. Watery food increases the amount of milk, but diminishes the percentage of solids.

6. The *function of the thyroid* is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the

sexual functions; (2) it is supposed to antagonize toxic substances; and (3) it produces an internal secretion.

Removal of the thyroid gland causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out, and the patient becomes unwieldy and clumsy in both body and mind. The complete removal causes death in most animals, and it is not considered justifiable in man.

7. The coagulation of the blood is due to the development in it of fibrin. In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleoproteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed; one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot. Lymph also coagulates, but less rapidly, because there is much less fibrinogen present.

8. The *respiratory center* is in the medulla, at the apex of the calamus scriptorius. (Subsidiary centers are also found in the spinal cord.)

9. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

10. They are all secretions, but urine is also (and chiefly) an excretion; perspiration and bile are also excretions.

11. *Immediate effects of cutting the sciatic nerve* would be: Loss of motion in all the muscles below the knee; also in biceps, semimembranosus, semitendinosus, and adductor magnus; anesthesia in same parts; vasomotor disturbances (the limb becoming first hyperemic, later colder and with diminished blood supply).

The remote effects would be: The divided ends retract and become bulbous; Wallerian degeneration occurs in the peripheral part; the affected muscles atrophy and the "reaction of degeneration" is observed; trophic changes occur in the skin.

12. *Causes of bodily fatigue:* Presence of sarcolactic acid and acid potassium phosphate in the muscle; using up of the material from which the energy is obtained, and accumulation of waste products.

13. *Superficial reflexes* are such as can be elicited by stimulating the skin. *Four examples:* The cremasteric reflex, plantar reflex, gluteal reflex, and abdominal reflex.

Deep reflexes are such as are elicited by stimulating tendons or muscles. *Four examples:* The patellar reflex ankle clonus, Tendo Achillis reflex, and triceps reflex (elbow jerk).

15. The *anterior* roots of the spinal nerves are efferent and motor, and cause contraction of the muscles to which the nerves are distributed.

The *posterior* roots of the spinal nerves are afferent and sensory, and are distributed to the skin.

There are thirty-one pairs of spinal nerves.

MATERIA MEDICA AND THERAPEUTICS.

1. ACONITE. (*a*) and (*b*) *Official preparations, with adult dose:* Fluid extract, ♏j; tincture, ♏x. (*c*) *Medicinal uses:* For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritis, herpes, chilblains, etc. (*d*) *Therapeutic effects:* First stimulates and then paralyzes heart and also sensory nerves; lowers blood pressure; dilates peripheral blood vessels; is a respiratory sedative; reduces body temperature; is a diuretic and diaphoretic.

2. STRYCHNINE. (*a*) *Indications for use:* Impaired digestion, cardiac weakness, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, some forms of paralysis, chorea, epilepsy, neuralgia, insomnia, alcoholism. (*b*) *Dosage:* 1/64 grain. (*c*) The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes, and death in from five minutes to six hours, usually within two hours."

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out and the patient is to be kept as quiet as possible."—(Witthaus' *Essentials of Chemistry.*)

4. The official preparations of arsenic, with their doses, are: Arseni trioxidum, gr. 1 30; Liquor acidi arsenosi, ♏vij; Arseni iodidum, gr. 1 20; Sodii arsenas, gr. 1 6; Sodii arsenas exsiccatus, gr. 1/20; Liquor potassii arsenitis, ♏vij; Liquor sodii arsenatis, ♏v; Liquor arseni et hydrargyri iodidi, ♏vij.

7. (*a*) *Nitroglycerin* dilates the arteries; (*b*) *Aconite* dilates the arteries; (*c*) *Digitalis* constricts the arteries; (*d*) *Veratrum viride* dilates the arteries; (*e*) *Strophanthus* constricts the arteries.

8. See below: PRACTICE OF MEDICINE, question 5.

9. *Podophyllin* is a slow, drastic, cholagogue cathartic; dose, gr. 1 4.

Cascara sagrada is a simple laxative; dose, gr. xv.

Aloin is a cholagogue purgative, acting mainly on the large intestine; dose, gr. j.

13. Pilocarpine hydrochloride is derived from Pilocarpus Jaborandi. The dose is gr. 1 5. It causes increase of saliva and of perspiration; increased peristalsis; it increases and then diminishes blood pressure and heart action; it causes the pupil to contract, and depresses the nervous system. It is used in Bright's disease, uremia, and whenever a prompt diaphoresis is required.

CHEMISTRY.

Urea has the formula $CO(NH_2)_2$; it "crystallizes in transparent needles or four-sided prisms, without Aq; permanent in air; odorless, having a cooling, slightly bitter taste, resembling that of saltpeter. Soluble in an equal weight of cold water, very soluble in boiling water and in five parts of cold water or one part of hot alcohol, the solutions being neutral in reaction. At 248° F. it melts, and slightly above that temperature is decomposed. It is found in the blood, chyle, lymph, humors of the eye, saliva, perspiration, bile, milk, serous fluids, amniotic and allantoic fluids, and especially in the urine.

"It is the principal product of the oxidation of protein substances in the animal body, and is the form in which most of the nitrogen is excreted."

2. Lithia and the salts of lithium are used in cases of uric acid diathesis, because: (1) They diminish the acidity of the urine; (2) they have a diuretic action; (3) they hasten the excretion of the urates; (4) and so prevent the accumulation of gravel and the formation of calculi; (5) the lithium salt of uric acid is the most soluble of all the urates.

3. The *normal composition of urinary calculi* is: Uric acid, sodium urate, ammonium urate, calcium oxalate, calcium phosphate, or ammoniomagnesium phosphate. More rarely: Cystin, xanthin, urates of potassium, calcium, or magnesium.

4. *Fermentation* is the decomposition of organic matter containing carbon, hydrogen, and oxygen only: it occurs in presence of a ferment. When it also contains nitrogen and sulphur the process is called *Putrefaction.*

Decay is slow combustion without the emission of light.

5. The chemical name for white arsenic is arsenic trioxide. It is a white, odorless substance; it has a faint metallic taste, is with difficulty soluble in water; it takes up oxygen readily. It is used in the manufacture of green pigments and of glass; as a vermin poison: to preserve material for dissection.

6. The atomic theory regards matter as not being infinitely divisible, but as being composed of indivisible particles called atoms. Dalton, by ascribing to each atom a relative weight as compared with the weight of other atoms, was able to explain and produce reasons for all the observed numerical laws of chemical combination.

7. The *chemical composition of bone* is: Tricalcic phosphate, magnesium phosphate, calcium carbonate, ferric phosphate, and organic matter (chiefly gelatinous matter).

8. The *principal pigment of normal urine* is urochrome.

9. *High specific gravity* of the urine may indicate: Diabetes mellitus, fevers, and chronic parenchymatous nephritis.

Low specific gravity of the urine may indicate: Diabetes insipidus, chronic interstitial nephritis, contracted kidney, some nervous disorders, albuminuria, hysteria

Transitory low specific gravity may indicate: Hysteria, or some nervous disorders, or the ingestion of an abnormal amount of fluids.

11. *Specific gravity* is the weight of any substance as compared with the weight of an equal volume of another substance taken as a standard under like conditions of temperature and pressure.

12. The *properties of bile* are: A greenish or brownish fluid, alkaline or neutral reaction, sweetish-bitter taste Specific gravity of about 1030, and it contains about 10 or 12 per cent of solids. The chief constituents are water and sodium glycocholate, sodium taurocholate, and pigments.

13. *Reaction* has two meanings: (1) The interaction of two or more substances causing a chemical decomposition; (2) the action of substances upon certain organic pigments, such as litmus.

Reagent is a substance used to bring about a reaction (first meaning above).

14. *Marsh's test for arsenic:* This test depends on the fact that arsenic hydride is formed when nascent hydrogen acts on a compound of arsenic:

$$H_3AsO_3 + 3H_2 = AsH_3 + 3H_2O.$$

A small flask fitted with thistle funnel and a delivery tube, as for the production of hydrogen, is used; pure zinc and hydrochloric acid are introduced, and after a short time the hydrogen is ignited. It is advisable to cover the flask with a cloth before igniting the gas, as an explosion may happen unless the air has all been driven out. If the materials are pure the hydrogen flame gives no deposit upon a piece of cold porcelain brought into it, but commercial zinc usually contains arsenic. When the purity of the gas is proved, a little solution of arsenite may be poured down the thistle funnel, which will produce a more rapid evolution of gas, and the flame will become larger and perceptibly colored. A piece of cold porcelain depressed upon the flame will be covered with a deposit of metallic arsenic. The films of arsenic are metallic looking in the thicker places, brownish near the edges; they are easily volatized by heat, and dissolve in solution of bleaching powder. A portion of the glass tube from which the gas is burned should be heated to redness ;the gas decomposes and a deposit of arsenic appears on the tube, which may be identified in a similar way, or may be converted into crystals of oxide by cautious sublimation in an open tube.—(Fisher's *Elementary Chemistry.*)

15. *In vegetable life* the metabolic changes are chiefly synthetic; the plant absorbs water and carbon dioxide and builds up complex substances.

In *animal life* the metabolic changes are chiefly analytic; the animal takes as food complex substances and splits them into simpler substances.

HISTOLOGY, BACTERIOLOGY, AND PATHOLOGY.

5. *To make a pure culture:* "All that is necessary is to inoculate the liquefied gelatin with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, to pour the liquid on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth."—(*Reference Handbook of the Medical Sciences.*)

6. Bacteria multiply by fission. A bacterium about to divide seems to be larger than normal, and if it is a coccus it becomes more ovoid; changes occur first in the nucleus, and the bacterium just falls in two. It has been calculated that a single bacterium could, by fission, produce two in one hour. Fortunately, they seldom obtain food enough to keep up this process for any length of time.

7. Koch's law in regard to the bacterial cause of disease is: (1) The microorganism must be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

9. *Cultural characteristics that differentiate the colon bacillus and the typhoid bacillus:* (1) On gelatin plates the colonies of typhoid develop more slowly than those of colon bacillus.

(2) the colon bacillus causes fermentation with production of gas in media which contain sugar; the typhoid bacillus does not.

(3) The colon bacillus produces a strong acid reaction and coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk.

(4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not.

(5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not.

10. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic microorganisms.

Susceptibility is the quality or condition of being liable to take a disease; it is the converse of immunity.

PRACTICE OF MEDICINE.

1. *Autointoxication* is the condition in which a person is (being) poisoned by the reabsorption of the waste products of his own metabolism, which should have been excreted. The source of the toxins producing this condition is the body of the person so suffering.

4. *Melancholia* is a form of insanity in which the patient suffers from excessive mental depression.

"*Dementia,*" when confirmed, consists in a total absence of all reasoning power and an incapacity to perceive the true relations of things: the language is incoherent and the actions are inconsistent; the patient speaks without being conscious of the meaning of what he is saying; memory is lost, and sometimes the same word or phrase is repeated for many hours together; words are no longer connected in meaning, as they are in mania and monomania."—(Taylor's *Medical Jurisprudence.*)

5. The Widal test for typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed asceptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. * * * A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology.*)

Its diagnostic value is believed by some to be great; others place little reliance on it. It may be absent in cases of typhoid fever; it may be present for several months after an attack of typhoid; the reaction may not be obtained till the third week of the disease; it may be present in other diseases or in perfectly healthy persons. The above have all been urged as objections; certainly only positive results have any value at all.

7. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine, moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, hemoptysis, slight fever, and night sweats.

8. In *paralysis of the third nerve:* Ptosis, outward deviation of the eye, paralysis of accommodation, diplopia, dilated pupil, and slight exophthalmos are present.

9. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease. *Organic murmurs* may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

HYGIENE AND MEDICAL JURISPRUDENCE.

1. *Disinfectants* are agents which restrain infectious diseases by destroying or removing their specific poisons.

Deodorants are substances which destroy the odorous products of putrefaction.

Germicides are agents which destroy bacteria and their germs.

Where spores are found the prolonged application of steam under pressure, or fractional sterilization, will be found efficient.

2. From the figures given the *birth rate* in Trenton would be:

$$\frac{1{,}075 \times 1{,}000}{90{,}000} = 11.9 \text{ per thousand.}$$

Similarly, the *death rate* would be:

$$\frac{1{,}324 \times 1{,}000}{90{,}000} = 14.7 \text{ per thousand.}$$

3. *Pettenkofer's method of determining the percentage of carbon dioxide in the air:* A large cylindrical container of known capacity, say, 15 litres, is filled with the air to be examined; a known volume of barium hydroxide is then added and shaken up with the air. The carbon dioxide combines with the barium hydroxide to form a barium carbonate, which is insoluble, and also incapable of acting upon an indicator. The barium hydroxide employed is of known strength, *e. g.*, it may be of such strength that 1 c.c. of the solution neutralizes 1 c.c. of carbon dioxide at normal temperature and pressure. If then we find that 10 c.c. of the barium hydroxide has been neutralized by the carbon dioxide present in the air, we know that 10 c.c. of carbon dioxide is present in 15 litres or 15,000 c.c. of the air examined.

4. A water is said to be hard when it contains in solution certain salts, such as calcium and magnesium salts, which are capable of acting upon soap and forming with it a curdy deposit.

To measure the relative hardness of water a standard soap solution is carefully added to a definite volume of the water until a thin, beady lather is produced. The amount of soap solution which must be added to produce this lather increases with the hardness of the water.

5. *Milk may be sophisticated or adulterated* by: (1) Skimming; (2) the addition of water; (3) the addition of coloring matter, such as caramel, annatto, or methyl orange; (4) the addition of preservatives, as boric acid, formaldehyde, salicylic acid, or salicylates; (5) the addition of arrowroot, flower, sugar, glycerine, chalk, or sodium carbonate.

12. *Prophylaxis of malarial fever.* Individuals should use mosquito netting round their beds and wire gauze in doors and windows, so as to keep out the mosquitos as much as possible. During residence in malarial districts quinine should be taken every morning before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darknesss, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also efficacious.

14. *Potable water* should be colorless, odorless, cool, limpid, soft; it should have an agreeable taste, neither salty nor sweet nor flat; it should dissolve soap readily without formation of a curdy precipitate; it should contain not more than about twenty-five to thirty grains of solids per gallon, and should not be polluted with sewage.

The sources and varieties of water have been classified thus:

Wholesome.	1. Spring water	very palatable.
	2. Deep-well water	
	3. Upland surface water	moderately palatable.
Suspicious.	4. Stored rain water.	
	5. Surface water from cultivated land	
Dangerous.	6. River water, to which sewage gains access	palatable.
	7. Shallow-well water	

15. The *impurities found in water* are: Sewage, leaves, surface washings, manufacturing refuse, lead, other metals, leakage from gas pipes, insects, fungi, bacteria, entozoa.

BULLETIN OF APPROACHING EXAMINATIONS †

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct. 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles.	Dec. 7
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven.	Nov. 9
Delaware	J. H. Wilson, Dover	Dover.	Dec. 14
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Oct. 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 10
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 12
Idaho*	W. F. Howard, Pocatello	Boise	Oct. —
Illinois	J. A. Egan, Springfield	Chicago	Oct. 20
Indiana	W. T. Gott, Crawfordsville	Indianapolis.	Jan. 11
Iowa	Louis A. Thomas, Des Moines	DesMoines	Sept. 21

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular state.

Alaska.—It is announced that hereafter physicians and surgeons desiring to practise in Alaska will be required to procure a license from the Federal authorities. The new law amending the Alaska code, which passed Congress February 6, provides that physicians must secure a license, which will be granted to members of the medical profession who have diplomas recognized by the Association of American Medical Colleges.

New Jersey.—At the annual meeting of the State Board of Medical Examiners, held at Newark on July 6, the following officers were elected: *President*, Dr. Chas. A. Groves, East Orange; *Treasurer*, Dr. A. Uebelacker, Morristown; *Secretary*, Dr. E. L. B. Godfrey, Camden.

Washington.—Changes have recently been made in the medical law of this State, to the following effect: The examination will be conducted in the English language, in writing, and must consist of at least ten questions upon each subject, none of which shall relate to treatment. The examination will cover the following subjects:

Anatomy, Histology, Gynecology, Pathology, Physiology, Bacteriology, Chemistry and Toxicology, Obstetrics, General Diagnosis, and Hygiene.

All applicants must obtain not less than 60 per cent. in any one subject; however, 5 per cent. on the general average is allowed for each ten years of reputable practice.

It will be noted that there are now fewer subjects of examination, and the passing mark has been reduced from 75 to 60 per cent.

Colorado now requires a practical examination in Regional Anatomy, Uranalysis, Pathology, and Physical Diagnosis.

Hemiphlegia from Cerebral Arteritis in Heredosyphilitics.—Paul Savy says that the early symptoms of syphilis in hereditary cases occur within three months of birth, and the dystrophies come from the fifth to the twentieth year. The manifestations of cerebral arteritis in the form of hemiplegia occur in the interim, the earliest recorded having been seen at five months of age. They occur from the second to the fifth year in general. They may be associated with other nervous troubles in cases that show evidences of syphilis, or they may occur suddenly in children that have given no evidences of syphilis. They may be preceded by symptoms of malaise or convulsions for a few days. Such hemiplegias may disappear entirely under specific treatment in a few weeks or months, or there may be left a variable amount of impotence and atrophy, corresponding to an area of brain softening due to obstruction of some one artery. These conditions are entirely similar to the specific hemiplegias of adults, which are often of a passing nature, and are caused by cerebral arteritis with ischemia. Whenever we have a sudden hemiplegia in a child we may look for syphilis, even if there are no other signs of its presence.—*Revue de Médecine.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of September 4, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	536	142
Diphtheria	185	11
Measles	116	4
Scarlet Fever	70	6
Smallpox	—	—
Varicella	10	—
Typhoid Fever	181	11
Whooping Cough	24	11
Cerebrospinal Meningitis	6	8
Malarial Fever	—	—
Totals	1,126	193

Relapsing Tetany.—Langmead reports the case of a girl of eight years who suffered from tetany associated with a greatly dilated colon. The case was very resistant to treatment, but finally improvement occurred under daily colonic irrigations and massage. Eleven months later a second attack occurred. During the interim, while there were no convulsions and an enlarged colon could not be demonstrated, the facial irritability remained. Langmead has observed seven cases of relapsing tetany associated with enlarged colon.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended September 3, 1909:

		CASES.	DEATHS

SOME PRACTICAL ASPECTS OF THE SURGERY OF THE PERITONEUM.*

BY W. A. NEWMAN DORLAND, A.M., M.D.,

PHILADELPHIA.

OF THE UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE AND OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

WE, as American physicians, may with pardonable pride claim the peritoneum as the masterfield of the American surgeon, without any possible charge of usurpation of foreign honors. It is an interesting fact that the successful management of the various peritoneal diseases, including appendicitis, is a distinct and lasting triumph to American surgery. Deaver, Fowler, Murphy, Morris, and Mayo have been names to conjure with. Before their resistless onset and the brilliant combination of their powerful mentalities and matchless and perfect technique the seemingly almost insuperable problems of peritoneal surgery have wilted and disappeared as at the touch of a magician's wand. The impossible has been accomplished. Led by these mighty men of valor, the little army of scientific American surgeons has pressed to the front and persisted in the van of surgical progress. Consequently the peritoneal cavity is no longer regarded with the fear and veneration with which our immediate forefathers worshipped it at a distance. The admonition, "hands off," is no longer posted above it for them, but only for those who, with deficient knowledge and unclean and faulty technique, would rush in where abler and more scientific men have paused and then cautiously entered. An increased knowledge of the peritoneal cavity and its vital organs and a greater familiarity with its surgical reactions have made it today a favorite field for the exploitation of new and ingenious technics. A surgical remedy for almost every intestinal and visceral complaint is now being eagerly sought. Witness the truthfulness of this assertion in the recently proposed and practised method of appendicostomy for the relief of amebic dysentery and tuberculous enterocolitis—a procedure which has been attended with very considerable and gratifying success.

As a direct result of this closer acquaintanceship with a most vital portion of the human body, various conditions which but recently defied the utmost skill of the ablest physicians are now but comparatively trifling affairs in the estimation of the progressive and up-to-date surgeon. Appendicitis, which twenty-five years ago was an unrecognized surgical entity, is to-day a simple condition to treat, if it be taken in its earliest stages; and peritonitis of idiopathic origin has been relegated to the limbo of medical follies. An early incision will quickly demonstrate a tangible cause in every case of acute peritonitis, and thorough asepsis, together with the application of the appropriate surgical technique, will almost invariably work a cure. It has, likewise, come to pass that puerperal sepsis, the *bête noir* of the older obstetricians, has, through modern antisepsis and advanced surgical treatment, lost much of its former grisly horrors. Free drainage, the semirecumbent posture, intestinal lavage, constant intrauterine irrigation, and careful peritoneal toilet have combined to lessen remarkably the mortality and morbidity of this unfortunate and formerly very fatal condition. It required many years of careful observation and cost many thousands of lives for the abdominal surgeon to learn that the danger-zone of the peritoneal cavity lay in the region of the diaphragm, and that if morbidity and mortality would be lessened the secretions of the cavity must be drained in the opposite direction—away from this freely absorbing surface. The adoption of this precaution has, in my hands as in those of every other surgeon, resulted most satisfactorily in the management of the severer forms of puerperal septic infection as well as in the graver varieties of general surgical infection of the peritoneum.

The Fowler-Murphy Method.—It is at this point that I wish to emphasize what I believe to be the most important advance in abdominal surgery that has been made, not only in the past decade but for many years prior to that period, as I have recently shown in a paper on "Ten Years' Growth in Abdominal Surgery" (*Medical Standard*, January, 1909). I think I am safe in stating that the Fowler-Murphy treatment of diffuse suppurative peritonitis stands preeminently as the greatest achievement to date of surgical progress in this field. This desperate condition, characterized by the presence of free pus in the peritoneal cavity, which only ten years ago in the hands of the ablest surgeons gave a mortality of 85 per cent., now yields a death rate of only 7 to 10 per cent., as far as the scanty statistics which are accessible will permit us to judge; and this wonderful improvement must be attributed entirely to the genius of the two men whose names are indelibly written upon the pages of surgery in connection with this subject.

What authority have I for speaking thus positively? Listen, if you will, to a few statistics bearing upon the matter. Eisendrath, of Chicago, in the *American Journal of Surgery* for last December (1908) reported 34 cases of general peritonitis with a mortality of 41 per cent., including patients operated upon during advanced stages of the condition as well as those encountered at the very onset of the infection. In 10 of the cases operated upon during the first twenty-four hours *but one died*—a mortality of but 10 per cent. In 10 operated upon on the second day there were 2 deaths—a mortality of 20 per cent.; while in 6 operations performed on the third day there were 2 deaths—a mortality of 33 per cent. As Eisendrath has indicated, these results compare very favorably with those obtained

*An address delivered in Pittsburg before the College of Physicians on May 27, 1909.

at the large European general hospitals, which he states as follows:

Moynihan	17 cases	18%	mortality
Carson	22 "	63%	"
Herzel	48 "	68%	"
Hagen	30 "	60%	"
Hirschel	65 "	54%	"
Körte	27 " (first 48 hours)	18%	"
	30 " (third day)	36%	"
Arnsperger	33 "	51%	"
Biondi	13 "	80%	"
Bode	30 "	33%	"
Lieblein	35 "	71%	"
Heidenhein	42 "	55%	"
Hotchkiss	28 "	17%	"

Murphy, who has given a careful resumé of this method of treatment in his admirable paper (*Surgery, Gynecology and Obstetrics*, June, 1908) reports 51 cases, including 5 typhoid perforations, with 100 per cent. recovery, these cases all being of exceptional gravity, while McGuire reports 18 cases with but one death, and other operators show results equally as gratifying.

A glance at these figures demonstrates conclusively that the Fowler position—or its modifications—when joined with proctoclysis, as suggested by Murphy, has proven the fortunate combination in overcoming one of the most horrible conditions the surgeon is called upon to combat, and if every case could fall into the surgeon's hands at the very onset of the infection we may safely assert that the mortality could be reduced almost to nothing. Now the wave of improvement rolls on, for Stuart McGuire (*Journal Am. Med. Assoc.*, March 8, 1908) has recently shown that there are certain objections which may be advanced against the semi-sitting position. Thus, it renders difficult the use of the bedpan; it is unnatural and subjects the patient to a mental and physical strain; and it permits of a slipping downward from weakness or during sleep whereby its value is annulled, since the abdomen at once becomes parallel to the surface of the bed as the result of a bending of the body at the costal arch. McGuire's suggestion of the elevation of the head of the bed, whereby a uniform flat inclined surface obtains, with an inclination at any angle that may be desired, will obviously meet these objections. An important point in this connection, and one which is frequently overlooked, is the necessity of insisting upon the assumption of this position from the moment the diagnosis is made, and not only postoperatively. In the older cases—those more than twenty-four hours advanced—gastric lavage should precede the operation, and in the severely poisoned cases intravenous saline infusion becomes most valuable. Where there is streptococcic infection, as shown by feeble leucocytic reaction, the use of antistreptococcic serum is indicated. Speed of operation—the incision generally being made in the lower right quadrant of the abdomen; a minimum of visceral manipulation; strict omission of peritoneal irrigation in order that the pus may not be washed toward the dangerous diaphragmatic zone; free drainage by means of rubber tubes over the pubes, at the site of perforation of the bowel, in Douglas's pouch, or wherever pus-pockets may be found; and, after the operation, constant proctoclysis with normal saline solution at the rate of 1½ to 2 pints every two hours, the patient resting in the semi-sitting posture—these are the steps of the now famous Fowler-Murphy treatment of diffuse suppurative peritonitis.

Some Aids in Peritoneal Diagnosis; the Morris Point.—Naturally enough, this concentration of the surgical mind upon the peritoneal cavity has borne its fruit in numerous suggestions and clinical observations, some of which will doubtless prove of permanent value. In this connection mention may most appropriately be made of the very valuable suggestion in diagnosis which was announced last year by that practical surgeon of New York City, Dr. Robert T. Morris (*Jour. Amer. Med. Assoc.*, Jan. 25, 1908). The famous McBurney point has become a landmark in anatomical topography, familiar to every surgeon. You all know its position (an inch and a half from the right anterior superior iliac spine on a line extending from that spine to the umbilicus) and its value in the diagnosis of inflammation of the vermiform appendix. Morris asserts that this point is only of secondary importance, and must give place in diagnostic significance to another point situated an inch and a half from the opposite end of the spino-naval line—that is, at a corresponding distance from the navel and about six inches distant from McBurney's point. This we may term the point of the right lumbar ganglia of the sympathetic nervous system. Tenderness over this spot is, according to Morris, of considerable significance, as follows: If the point show tenderness to any degree, even if pressure over McBurney's point elicits no tenderness, there will inevitably be found a chronic or subacute inflammatory condition of the vermiform appendix, provided that the corresponding point to the left of the umbilicus (the point of the left lumbar ganglia) shows no tenderness upon pressure. If both right and left lumbar ganglia are sensitive to pressure, the trouble lies in the pelvis—in the Fallopian tubes or ovaries; while absence of tenderness over either of these ganglia in the presence of obscure abdominal symptoms will indicate trouble above the region of the appendix. As a rule, generalizations are dangerous and uncertain, and dogmatic clinical statements are apt to stumble against individual peculiarity or idiosyncrasy, much to their undoing. If this observation be true, however—and Morris speaks with considerable assurance after a careful and prolonged investigation—then we have here an excellent addition to our means of diagnosis of pelvic and abdominal pathology, and one with which we should all thoroughly acquaint ourselves. I wish to state that during the past year I have found this Morris point a valuable aid to me in my abdominal explorations.

The Peritoneal Face.—At this point let me call your attention to another aid in diagnosis which most of the textbooks and surgical writers have failed to emphasize and even in many instances to mention at all. It seems to me that it should be written in capital letters, for I believe it to be a symptom of the utmost importance, and one which, if generally recognized and followed, would be responsible for the saving of many valuable lives. I refer to that peculiar and unmistakable expression of the face which I here designate as the *peritoneal face* or *facies peritonæi*, which is as striking as is the ovarian *facies* or that characteristic of Parkinson's disease. It is also known as the *facies abdominalis*, and can best be described as a pinched, anxious, furrowed face, with the nose and upper lips drawn up. When present it indicates grave abdominal disease, and should be regarded as a positive indication for operative intervention. It is not infrequently to be noted in the

absence of every other symptom of peritoneal involvement, and is probably an indication of a profound disturbance of the delicate and sensitive system of splanchnic nerves resulting either from the pressure exerted by morbid exudates or from a certain degree of toxemia. Practically the same condition prevails in the shock following a blow or injury to the solar plexus.

It was on the strength of the peritoneal face alone that I performed my first operation in your portion of the state about four years ago. At 11 o'clock at night I was called by long-distance telephone from Uniontown, and asked to take the midnight train for Pittsburg in order to operate upon a case of appendicitis the following morning. When I saw the patient, a woman 32 years of age, at 10 o'clock that morning all her symptoms—which had been urgent the night before—had disappeared. There was not even abdominal rigidity. Her facial expression, however, was one of most intense anxiety, and this, coupled with the history of an acute suppression of the symptoms, decided me to proceed with the operation. I found not only the appendix for one and a half inches the seat of gangrenous change, but for two inches around the mesentery was hard and green. Had I been deceived by the apparent improvement in the patient's condition death would have supervened in from twenty-four to thirty-six hours.

Only recently I was deeply impressed by the general overlooking of this truly vital symptom in a case of unusual interest. On a certain Monday I was called to West Philadelphia by a physician to see with him a man, 40 years of age, who presented a remarkable condition. On the preceding Friday while riding his bicycle he suddenly found himself almost overrun by a heavy wagon, and saved himself only by grasping the tongue of the vehicle. The violent exertion caused him to collapse, although apparently uninjured, and he was sent to his home in a carriage. His one symptom, as I learned from his family physician, was an obstinate constipation, which had failed to respond to the usual remedies, including large doses of salts and rectal enemata. When I saw him, three days after the accident, his temperature was normal and pulse 72; there was no history of pain, and the abdomen was flaccid and permitted an easy exploration of its contents. There was noted a movable dullness on percussion, and a peculiar doughy sensation on palpation. Upon entering the room I had observed an expression of extreme anxiety on the patient's face, and, notwithstanding his assurance of perfect comfort, I advised his immediate removal to the hospital. Four hours later I found the resident physician engaged in taking the patient's history and on making inquiry he informed me there was nothing the matter with the man. Learning that the surgeon was in an adjoining ward I suggested he see the patient at once. This was done, and carefully going over the case he assured me he saw no indication for immediate surgical operation, but that if I said so he would do an exploratory incision. Gentlemen, when I saw the patient was dead—died on the operating table. The incision had revealed an [illegible] about the size of [illegible]

the peritoneal face, and its main signification to the surgeon—immediate surgical exploration of the abdominal cavity.

Intestinal Localization.—What abdominal surgeon has not been confronted by the perplexing question, "With what portion of the intestinal canal am I dealing?" when a traumatism or his incision has revealed the loops of underlying bowel. True it is that to a certain extent the location of his wound or incision will afford a strongly presumptive diagnosis as to the portion of gut immediately involved. It has remained, however, for the patient investigations of another of our American surgeons to elucidate this matter as no other man has done; and Monks (*Jour. Am. Med. Assoc.*, April 3, 1909) has given us the results of his indefatigable labors in this direction. Stated briefly, he informs us that if the incision lie in the upper portion of the abdomen, especially in the middle line or to the left of it, any loop of small intestine encountered will in all probability belong to the uppermost third of the gut; if the incision lie in the middle portion of the abdomen or in the left iliac region, the intestinal loops belong probably to the middle third of the gut; while if the incision is located in the right iliac fossa or to the right of the rectus muscle, or even in the median line between the umbilicus and the pubes, the intestinal loops will probably belong to the lowest third of the small bowel. This is all very interesting and of undoubted practical value, but to the average surgeon it is but the concise presentation of a hitherto recognized anatomical fact. Monks, however, supplements this primary statement by two other pronunciamentos that carry the impression of newness and confer upon the question of intestinal localization an intensely practical aspect. In the first place, he emphasizes the importance of the distinctive anatomical characteristics of the upper and lower portions of the small intestine in determining the portion of gut involved in any surgical operation. Concisely stated, these local peculiarities are as follows: The loops of the upper bowel are of large calibre, have thick walls, are extremely vascular, and have numerous valves which can readily be felt through the walls. The attached mesentery is generally thin and readily shows the blood-vessels, which are large, long and straight, and radiate to the bowel from primary arches deeply located in the mesentery. The loops of the lower bowel, on the contrary, are thin, of small calibre, of moderate vascularity, free from valves; while the attached mesentery contains more fat, as a rule, and is short, small [illegible]

ileo-cecal valve. Note, if you please, that the important point here is an absence of twisting of the mesentery. This suggestion of Monks will appeal to every surgeon as a valuable addition to our intra-abdominal diagnostic means and an excellent method of simplifying the intricate and delicate surgery of the bowel.

The Significance of Left-Sided Pelvic Pain; Redundant Sigmoid.—One other diagnostic suggestion of recent development. We frequently hear of the interrelationship existing between right-sided tubal disease and appendicitis, and discussions have been numerous and interesting in the effort to determine conclusively which pathological condition generally precedes the other. At any rate, there has never existed an element of doubt as to the cause of right-sided pain in any given gynecological case; but, from the pioneer days of gynecology as a distinct branch of surgery, pain in the left lower quadrant of a woman's abdomen has invariably been ascribed to the ovary. Now we are told (Clark, *Pennsylvania Med. Jour.*, April, 1909) that in many of these cases, especially those associated with obstinate constipation, the ovary is not the offending organ at all, but that all the trouble and suffering arise in a curious condition of the sigmoid flexure to which the term "redundant sigmoid" has been given. Kelly, Clark, and others have called attention to this bowel-defect, and have emphasized the fact that many a healthy ovary has been sacrificed uselessly in the effort to relieve pain and neurasthenic manifestations resulting from a diseased sigmoid, which closely resembles the congenital condition known as Hirschsprung's disease, but which is probably due, as Clark has shown, to an unequal growth of the large intestine after birth. If the usual order of events in the development of the individual should hold true, and the colon should rapidly increase in size while the sigmoid flexure retains its normal infantile growth, no trouble of the kind in question will result. If, however, the sigmoid flexure should participate in the growth of the rest of the colon at an equal or even a minimum rate of growth, there is then produced the curious condition of redundancy which has been noted in this class of cases. According to the position occupied by the loops of redundant sigmoid will be the clinical manifestations of the disease. In whatever position [illegible] left-sided pain in the region of the ovary [illegible] a prominent feature; if the loops rest in [illegible] bladder increase [illegible] frequency of urination [illegible] if they lie in Douglas's pouch a [illegible] location after [illegible] reaction. quiry or observation, and the learned gentlemen probably really do not know just exactly how most comfortably to treat so harmless an affection any more than they would, as a rule, know how best to relieve an ingrowing toe-nail or remove a wart. Yet, some people seriously, and quite properly, wish to be rid of warts, and I have known one or two most successful physicians who built up large and widely useful practices upon the actual groundwork of their skillful treatment of acute coryza. I shall offer here as a subject for discussion a condition which is, *per se*, equally as harmless, as common, as simple, and, I may add, equally as important as acute coryza—if not more so.

Through a reasonably careful search in the Surgeon General's library, in Washington, the first reference I find to the noting of connective tissue adhesions across the fossæ of Rosenmuller, or of the significance of granulation hypertrophies in the fossæ, is in an article by Dr. Goodwillie, in the *New York Medical Journal*, August 24, 1889, entitled "Deafness from Nasal and Dental Diseases."

In the Manhattan Eye and Ear Hospital Reports, New York, 1894, I, 98, Dr. W. C. Phillips writes of "A Case of Extensive Adhesions Between Both Eustachian Tubes and the Vault of the Pharynx; the Result of Adenoid Growths."

Dr. R. C. Myles, in The Transactions of the American Otological Society, 1897, VI, 506, writes on "Pathological Conditions of the Ear, with Attending Phenomena, Apparently Caused by Synechiæ of the Eustachian Tube to the Tissues Over the Basilar Process and the Rhinopharyngeal Wall; A Report of Two Cases."

In 1902 Professor A. Politzer, in his work on Diseases of the Ear, speaking of Rosenmuller's fossa, says: "Chronic nasopharyngeal catarrhs often give rise to cystic hypertrophy of the adenoid tissue and the formation of large gaps and bridge-like bands."

Dr. Royet of Lyons in the *Bulletin de Laryngologie, Otologie et Rhinologie*, Paris, 1904, VII, 248, has a brief but pithy article on the "Syndrome Which is the Result of Tubopharyngeal Connecting Bands; Especially from the Otologic Point of View;" and again, in the *Revue Hebdomadaire de Laryngologie, d'Otologie et de Rhinologie*, July 7, 1906, he speaks of marked vertiginous and neurasthenic phenomena due to adhesions betwen the posterior wall of the pharynx and the Eustachian prominence.

In the *Journal of the South Carolina Medical Association*, June, 1906, I pointed out the importance of attention to adhesions and granulations in the fossæ of Rosenmuller in connection with certain common aural affections; and again, in the *Journal of the American Medical Association*, May 16, 1908, p. 1600, I emphasized these facts, and further briefly pointed out other common immediate and remote symptoms consequent upon the existence of the formations.

In the *Laryngoscope*, August, 1906, Dr. T. L. Brunk speaks of the practical importance of these pathological conditions in the fossæ; and in the same journal, for March, 1907, Dr. E. Pynchon refers to the importance of the treatment of these conditions.

This, so far as I am aware, covers the existing literature on the subject.* I have met with no other explicit references to these pathological formations in the principal modern text-books which I have consulted. In the past two years numbers of laryngologists, both in this country and abroad, have told me in conversation that while in a general way they supposed such conditions to exist occasionally, yet they never deliberately looked for such lesions in the fossæ, and seemed disposed to regard them as being of conspicuously minor importance. Indeed one laryngologist of national reputation in this country, to whom I carried a patient with a number of fibrous bands across the fossæ and masses of granulations half filling these hollows, after an apparently careful examination calmly looked at me over the top of his spectacles and informed me that he could not recognize the conditions of which I spoke. Thereupon he simply advised the carrying out of the old worn-out routine treatment for the deafness, severe tinnitus, and occasional vertigo, accompanied by neurasthenic symptoms causing more or less serious embarrassment. This patient was soon after operated upon with the result of a complete cessation of the vertiginous and neurasthenic manifestations, and great improvement in the hearing and tinnitus. In all, I have up to this time operated in about 200 cases presenting these very common lesions. In no case has some symptomatic benefit failed to accrue; while, as a whole, the results have been remarkable.

As has been pointed out before, these formations in the fossæ of Rosenmuller consist apparently (1) of mucofibrous bands, or webs (like the web of a duck's foot), generally in a plane perpendicular to the long axis of the fossa, and (2) of masses of what seem to be granulation tissue or hypertrophied glandular (lymphoid) tissue, similar to the familiar soft adenoid, lying above, below, and between these bands, sometimes quite filling the fossa, and at times extending down into the oropharynx behind the posterior faucial pillar (lateral pharyngitis).

As the bands are found almost invariably in persons who have passed the period of adolescence, and in whom a lymphatic tendency has existed, it is not unreasonable to consider them as being, to some extent, the residua of an old adenoid, which may or may not have been operated on. Indeed, it has been my experience to note that practically all adenoid hypertrophies of sufficient size to be an obstructive factor are adherent to the surfaces in the fossæ and to the posterior lip of the Eustachian cushion; and a proper removal of the adenoid cannot be accomplished without first breaking up the adhesions with the finger. Any postnasal swelling causing obstruction and mouth-breathing would necessarily favor the formation of these adhesions, because the very act of mouth-breathing, by rapid evaporation of saliva, makes the act of deglutition much more infrequent, thus leaving the swollen adjacent structures in the nasopharynx in more undisturbed contact.

The normal movement of the Eustachian tube is inward, upward, and backward, ranging from one-quarter to three-eighths, or even one-half of an inch, the two orifices sometimes almost meeting in the middle of the nasopharyngeal space, and it is quite clear that adhesions and granulations in and across the fossæ must exercise marked inhibitive influence on the tubal excursion.

The symptoms which follow upon the appearance of these lesions are due to (1) interference with the proper functionating of the Eustachian tube.

*Since writing the above there has come to my attention a valuable practical article by Dr. Francis P. Emerson of Boston, in the *Annals of Otology, Rhinology and Laryngology* for September, 1907, entitled "Rosenmuller's Fossæ and Their Importance in Relation to the Middle Ear."

upon which is so intimately dependent the integrity of the middle ear; (2) inflammation, by continuity, from infection lodging in and upon these lesions; (3) mechanical irritation caused by pressure and traction on the fibers of the stylopharyngeus, palatopharyngeus, and the constrictors of the pharynx; and (4) reflex irritation, the manifestations of which are common in pathological conditions of any highly sensitized area in the body. As many and various combinations of these causes may produce symptoms in different cases, it will be seen at once that the symptomatology of the affection is of relatively rather large scope, and it is strange for this reason, if for no other, that the importance of the condition has not, up to this time, been fully recognized.

Many cases of so-called catarrhal deafness are the common and serious consequence of unrecognized or neglected adhesions and granulations in the fossæ of Rosenmuller. The changes in the tympanic membrane, tinnitus aurium (opprobrium medicorum), the impairment of ossicular motion, the anomalies of sound conduction, the closed Eustachian tube, may all be due, directly or indirectly, to the lesions in the fossa. There may be present a deep, dull pain, perhaps better referred to as a malaise, in and about the ears, at times radiating to neighboring parts. Stuffiness and fullness in the ears and itching in the external meatus may be complained of, and there is often a tense, drawn, uneasy feeling extending from the ears down the throat and neck, behind the angles of the jaws. Sometimes the patient is quite unable to locate the discomfort with precision, but will recognize its source the moment it is touched with instrument or finger. There is often present the common sensation of popping or cracking in the ears while swallowing, or yawning, or otherwise moving the jaws. A persistent and irresistible desire for frequent yawning may be noted. Long-continued and distressing attacks of sneezing can, sometimes at least, be controlled by a thorough clearing out of the fossæ.

There is always present in some degree a form of postnasal catarrh. The so-called lateral pharyngitis, so resistant to ordinary routine treatment, is always a development of the fossal lesions, as are also many cases of follicular pharyngitis; and these cases will show prompt, satisfactory, and permanent improvement only after attention has been directed to the fossæ. The bands across the fossæ form pockets which are ideal lodging places for mucus and dust and infection of any sort that may be inspired by the patient, and, with these places as foci, irritation and inflammation easily and naturally extend to neighboring structures. The sensation of a lump or obstruction in the throat, simulating globus hystericus, may be noted.

The periodic or occasional laryngeal irritability and mild congestion, with hoarseness or an irritating cough, that is sometimes met with, and for which no cause is readily found, is most often due to the nasopharyngeal irritation accompanying these fossal lesions. Furthermore, this cough, if unrelieved, may, by mere mechanical action, bring about bronchial involvement of otherwise unaccountably intractable character. I have seen such a case, with severe and distressing cough and raucous voice, which had been diagnosed and treated as chronic bronchitis, and even as suspected tuberculosis, and in which recovery occurred after the removal of the adhesions in Rosenmuller's fossæ.

Symptoms of vertigo, doubtless largely due to the tubal and middle ear involvement, are not infrequently complained of. Distinct mental depression and the phenomena of nervous derangement may result from the constantly recurring attention of the patient to the unlocated and therefore unrelieved uneasiness and annoyance.

The diagnosis of the condition as described above is not at all difficult for the skillful user of the rhinoscopic mirror. Having once been seen and recognized, its pathological importance is deeply impressed upon the mind, and the presence of the lesions will seldom again be overlooked.

When found, these formations should be removed whether or not marked symptoms are presenting, for their removal is harmless, while their presence is certainly pathological and ultimately certain to be fraught with discomfort, if not with real danger. It may be said in passing that there is reason to believe that the unintentional breaking of these bands with the end of the nasal saw has given to ears and throats a relief which has been improperly credited, at times, to the removal of a small septal spur, and the same good though accidentally acquired effect can, I believe, fairly be attributed sometimes to the energetic use of the curved postnasal applicator.

The treatment is simple, and under thorough cocainization entirely painless. The index finger is passed through the mouth into the postnasal space and the fossæ are firmly and completely swept, to their very bottoms, of all obstructing formations; first one side and then the other being attended to without withdrawing the finger. This is followed by the application of a solution of nitrate of silver or argyrol. A few days' after-treatment with the same application usually suffices. Where catarrhal deafness has been the principal indication for this procedure routine treatment with catheterization should be persisted in until no further improvement appears.

The results of clearing out the fossæ when indicated may be said to be universally good, sometimes brilliant, and often immediate. It should be stated, however, that where the hearing has been impaired by the existence of these lesions to the point where, roughly speaking, it is possible to hear an ordinary watch only upon contact with the auricle, the outlook for an increase in the hearing is not good, though the progress of the disease be checked; the best results being gotten where the hearing for the watch is still as much as four or five inches or more away from the auricle, and in the more recent cases. It is fair to say, further, that if a long-standing symptom of these lesions, such as chronic irritative cough, or persistent neurotic manifestations, or tubal atresia, has produced a fixed habit or organic changes elsewhere, we cannot expect an immediate cure by the simple removal of the original cause. In the great majority of cases, however, where any of the above enumerated symptoms exist with obscure etiology, a careful examination of the nasopharynx will surely reveal the causative lesions in the fossæ of Rosenmuller, and attention intelligently applied to their removal will be productive of most satisfactory results.

In conclusion, I would say that the occurrence of these formations is so common, yet apparently so widely ignored; their logical significance so marked and so serious, yet their treatment so simple withal, that I have thought it justifiable to invite to them once more the earnest attention of the laryngologist, the rhinologist, and the otologist.

THE INFLUENCE OF METEOROLOGICAL AND CLIMATIC CONDITIONS ON METABOLISM.*

By JOHN BENJAMIN NICHOLS, M.D.,

WASHINGTON, D. C.

That external conditions exert a potent influence on the processes of body metabolism may not only be inferred from *a priori* considerations, but has also been clearly established by experimental investigations. Metabolism, it may be recalled, consists largely of two sets of processes, heat or energy production (thermogenesis) and heat dissipation (thermolysis). Heat is produced by the oxidation of material from either (1) the food, or (2) the body substance; under ideal dietetic conditions the energy produced should be derived entirely from the food, without any drain on body material. The heat generated in the body is eliminated in several ways. These two processes of heat production and heat dissipation are closely coordinated and controlled by nervous action, the heat-regulating mechanism. The heat regulation effects a balancing of heat production and heat elimination, and in such a way that a more or less uniform temperature of the body is maintained.

The production of energy or heat in the organism depends largely on the escape or elimination of heat from the body; and as this escape or dissipation of heat is influenced to a great extent by the external conditions surrounding the body, it will be readily seen that atmospheric conditions, which directly influence heat elimination, in like measure indirectly control oxidation in the body, and hence have practical dietetic bearings.

The main avenues by which the energy or heat produced by oxidation escapes from the body are three, namely: (1) radiation and conduction, (2) vaporization of water in perspiration and expired air, and (3) external muscular work.

The elimination of body heat by radiation and conduction is accomplished through the imparting of heat from the surface of the body to surrounding objects and the atmosphere.

The loss of heat by vaporization of water consists in the absorption of heat by water when passing from liquid into gaseous form. Each gram of water vaporized and so excreted by the skin or lungs absorbs 0.592 calory of heat from the body, and a large amount of heat is eliminated in this way.

The energy involved in accomplishing external work, which can be measured in terms of heat, will vary in proportion to the voluntary muscular activities of the subject. Like mechanical engines, however, only a fraction of the energy expended reappears as external work. For example, the mechanical efficiency of a steam engine is about fifteen per cent.; that is, only fifteen per cent. of the energy yielded by the burning of the fuel is converted into actual work. Similarly, the efficiency of the human body as an engine has been determined (Atwater and Benedict) as from thirteen to twenty per cent. It follows from this that for every calory of energy of external work that is produced, four to six additional calories of heat are generated by the body to be dissipated by radiation-conduction and vaporization.

*Read before the American Climatological Association, June 4, 1909.

An example of the relative magnitudes of the three main avenues of heat elimination is afforded by the calorimetric observations of Atwater and Benedict. The results of their observations in various tests average (per diem per person) as follows (Bulletin 175, Office Experiment Stations, U. S. Department of Agriculture, p. 152, 179):

	Five Rest Experiments (10 Days)		Six Work Experiments (14 Days)	
	Calories	Per Cent	Calories	Per Cent
Heat or energy production from oxidation of food and body material, as measured	2,258		5,179	
Heat or energy eliminated, as measured:				
Heat of urine and feces given off	17	1	21	4
Given off by radiation and conduction	1,741	77.1	3,850	74.0
Given off by vaporization of water	512	22.8	791	15.2
External muscular work measured			549	10.4
Total heat given off	2,270	100.0	5,214	100.0

In the foregoing experiments the temperature of the chamber occupied by the subjects experimented on was 20° C., and the humidity of the contained air ranged mostly from about 50 to 79, averaging 67 per cent.

The atmospheric conditions that especially affect the escape of heat from the body are temperature, humidity, and wind.

The temperature of the air influences both radiation-conduction and vaporization.

The greater the difference between the temperature of a body and the surrounding air and objects, the greater is the radiation and conduction of heat from the warmer to the cooler. Consequently the body gives off more heat in a cold than in a warm environment, and to make up for this greater loss body oxidation and metabolism are increased under the action of the heat-regulating mechanism. As the surrounding temperature rises, the heat loss by radiation-conduction and the total metabolism or oxidation correspondingly diminish. When the temperature of the air becomes equal to that of the body, no further loss of heat by radiation-conduction can take place, and all heat elimination must then be by evaporation. Experiments show that the total oxidation decreases as the surrounding temperature rises until a minimum is reached at about 33° C. If the temperature rises above this point another factor becomes operative, namely, overwarming of the body cells, which again causes increase of body oxidation.

The effect of atmospheric temperature on vaporization of water is the reverse of that on radiation-conduction. At the colder temperatures there is less evaporation, and hence less heat loss in that way; while at higher temperatures vaporization and heat-loss thereby are increased.

The effect of the surrounding temperature on metabolism has been abundantly shown by experiments. As an example may be cited the following results obtained by Rubner on the elimination of heat by a fasting dog exposed to different temperatures (Max Rubner, Die Gesetze des Energieverbrauchs bei der Ernährung, 1902, p. 106, 193). The distribution of the heat loss between radiation-conduction and evaporation and the nitrogen metabolism are also shown.

The nitrogen metabolism is not affected by changes in the surrounding temperature, the energy-yielding factors in the diet being involved rather than the tissue-forming.

Temperature	Total heat given off per kilo of body weight	Heat given off by radiation-conduction		Heat given off by vaporization of water		Nitrogen excreted in urine
C.	Calories	Calories	Per Cent.	Calories	Per Cent.	Grams
7°	86.4	78.5	90.9	7.9	9.1	1.52
15°	63.0	55.3	87.8	7.7	12.2	1.56
20°	55.9	45.3	81.0	10.6	19.0	1.80
25°	54.2	41.0	75.6	13.2	24.4	1.42
30°	56.2	33.2	59.1	23.0	40.9	1.56
35°	68.5	....	....	....	....	....

The humidity of the atmosphere influences the escape of body heat mainly through affecting the evaporation of water. In a dry atmosphere vaporization is favored; in a humid atmosphere evaporation is lessened; while in an air saturated with moisture escape of body heat by evaporation would be entirely prevented. A cold humid atmosphere also favors heat loss, supposably by the increased conductivity for body heat of damp clothing or skin covering. Total metabolism or oxidation is increased both by warm and by cold humid air; by warm humidity through overwarming of the body cells from the obstruction to heat loss effected by lessened evaporation; by cold humidity in compensation for the increased loss of heat by conduction.

Winds, and even imperceptible air currents, markedly favor heat loss, by increasing both radiation-conduction and evaporation.

It will be seen that in an atmosphere having the temperature of the body loss of heat by radiation-conduction would be completely checked, while in air saturated with moisture loss of heat by evaporation would be blocked. If both these conditions should coexist, practically all means of heat escape would be cut off, and the organism would be greatly embarrassed. With heat elimination obstructed, and oxidation and heat production undiminished (or even increased through the overwarming of the body cells), the temperature of the body must necessarily rise; and while this rise would again somewhat favor radiation-conduction, yet the conditions would be very oppressive and even dangerous. These considerations explain why the combination of great atmospheric heat and humidity brings about so great bodily discomfort, and introduces just the conditions favoring the incidence of heat-stroke or insolation. Muscular activity under these circumstances is especially trying, on account of the excess of heat generated, and the difficulty of its elimination.

There are other factors that influence heat dissipation and metabolism, and concern hygiene and diet, which do not properly pertain to atmospheric conditions. Clothing, for instance, acts as a shield against heat loss, and hence economizes oxidation. At the higher temperatures it is important that the clothing should retard heat dissipation as little as possible. Obesity also is a factor. An abundance of subcutaneous fat, by presenting a relatively less body surface for heat dissipation, and by protecting against radiation-conduction and evaporation, lowers metabolism. At higher temperatures with humid air heat loss is so much interfered with in obese persons as to cause them to suffer more distress under these circumstances than slender subjects.

These considerations, based on experimental demonstrations, indicate the need of a generous diet in cold weather or cold climates to make up for the greater heat loss. There is no necessity for an increase of nitrogenous food in the cold, as energy-yield only is needed, for which purpose fat and carbohydrate admirably serve (also alcohol?).

In hot humid weather it is especially important, for the individual's comfort and safety, that heat elimination be adequate. Heat production should be reduced to a minimum, as by avoiding muscular activity. The diet is not the greatest factor affecting the amount of body oxidation, as any excess of food not required to be burned up to provide for the body activities is stored up in the body. However, excess of food does to some degree increase body oxidation, carbohydrate least, and protein much the most. Hence is indicated rather spare diet in hot weather, especially of nitrogenous food. However, in obese persons a spare protein diet might be of advantage, through its effect in diminishing the store of body fat and so improving the conditions for heat dissipation.

ANESTHESIA IN THE CONTROL OF INFLAMMATION.

By JOHN W. WAINWRIGHT, M.D.,
NEW YORK.

It is claimed that if irritation is prevented by anesthetics, inflammation will not develop, or if it is already in evidence that local anesthetics will control it to the extent that it is comparatively harmless. If there is irritation of the sensory nerves or filaments through injury of any character, and the nerves can be reached by application of any of the agents which relieve pain sufficiently early, and the anesthesia can be continued, inflammation will not supervene. Irritation precedes inflammation and is always accompanied by pain; hence the control of irritation allays pain, and antagonizes inflammation.

Spiess, writing in the *Münchener medizinische Wochenschrift*, No. 8, 1906, declares that whenever the appearance of pain can be prevented, inflammation is also prevented. Rosenbach makes application of general anesthesia through weak doses of morphine for effecting a depression of the irritability of inflamed tissue. Spiess reports strikingly favorable results on the use of local anesthesia; he has through experimentation proven that the Jensen mouse tumor (carcinoma) is favorably influenced by the injection of anesthetics; that under certain conditions its growth is interfered with. Fischer produced a typical epithelial proliferation by injecting scarlet oil. "If we assume," he writes, "that certain substances—attraxins—accumulate in the organism and arise continually, exerting a sufficiently strong chemotactic action on the cells of a misplaced tissue fragment, the result must necessarily be a constant, limitless growth of these cells—a malignant tumor. If we admit this, and the statement of Spiess that mouse cancers can be cured with local anesthesia, we must admit the theory of a chemotactic action in the production of malignant growths. Local anesthetics can act either directly or indirectly on attraxins or tumor-producers, throwing them, as it were, under certain circumstances out of function. They arrest the further growth, and even lead to the cure of cancer."

As is well known, local anesthetics act upon exposed nerves as soon as they come into contact with them, rendering them insensible. They act upon the sensory nerves only, with no demonstrable effect upon the width of blood-vessels. This in

contrast to the ischemic action of cocaine, and the suprarenal principle which first reduces the capacity of the vessels to be followed by a dilatation: hemostasis, congestion. Spiess applied local anesthesia therapeutically in a series of operations in the throat, on the tongue, cheeks, lips, etc. If superficial analgesia was not sufficient, submucous injections were resorted to; all depending upon securing such frequent and intimate contact of the anesthetic with the lesion that all subjective painful sensations were checked entirely or reduced to a minimum. The subjective sensibility will correspond to the appearance of the wound and the degree of irritation. When pain is wholly absent or only unilateral the tissue may be regarded as non-inflammatory. In operative procedures the site of the needle-puncture itself should be made anesthetic before insertion into the tissue in order to avoid pain.

In minor injuries of the tongue, says Fischer (*Deutsche Monatschrift f. Zahnheilkunde*, XXV., April, 1907), due to sharp angles of the teeth, etc., in small vesicles at the margin of the tongue distinguished by intense pain, the subjective disturbances vanish after a series of anesthetizations given in rapid succession.

Coryza, if treated with local anesthetic insufflations is relieved by removing the irritation in the nasopharynx, thus bringing the tissues into a normal condition.

If these agents are rubbed into small cutaneous abrasions, lacerations, etc., or into wounds produced by the stings of wasps, bees, mosquitos, or other insects, in the form of solution or thick watery paste until the pain has disappeared, the friction does not produce redness or swelling, but, on the contrary, the swelling disappears, the wound becomes pale and insensitive, while the wound edges approximate and favor instant healing.

These observations have established the fact beyond cavil that local anesthetics remove pain, and that if this action can be maintained by continuous anesthetization, wounds heal without inflammation. If inflammation is already in evidence, it is made to disappear in short order. This action cannot be attributed to an antiseptic influence, for the anesthetics have no such property. It would seem, therefore, that the abolishment of pain and irritation must be the explanation of the beneficial results.

Sleep in which sensibility is depressed is favorable for the course of disease. The vexatious secretions of catarrhal coryza, for instance, almost cease during sleep, indicating hypoesthesia. In mild inflammations, sleep-hypoesthesia renders the inflammatory irritation inactive; the vasomotor reflex present in waking hours is not produced, secretion is lessened, and, in the case of coryza, the subjective symptoms are absent.

Numerous researches have shown that redness rises and falls with the presence or absence of pain. Also that an inflammation at its acme of development may lose its redness in a short time by the use of anesthetics; a result not obtainable with antiphlogistics. The disappearance of redness can be explained as follows: (1) An excitation of sensory nerves by reflex causes hyperesthesia; the suppression of this excitation can either prevent the development of hyperemia or remove it if already present. (2) The remedy influences the sensory nerves alone, and the vessels retain the normal play of their functions. (3) Anesthesia is required only to the extent of abolishing reflex action, which starts from the sensory nerves of inflamed tissues.

These postulates apply to anesthesia of hysteria and insanity. A sufficient number of cases have been reported to establish the claim that injuries, burns, etc., in these patients heal promptly without reaction. Laparotomized insane patients have been known to tear off the dressings, and to play with the wounds with their dirty hands, and still the wounds have healed promptly and smoothly. Hysterics, as is well known, can stick pins or needles through their skin without unpleasant consequences following. Cases, in fact, have been reported where in general anesthesia the patient was not scalded by boiling water. This can be explained on the supposition that the receptory nerves could not be irritated; the influence of heat being of short duration, a direct thermic action on the tissues is absent. Animal experiments made under special anesthesia corroborate these findings.

It is seldom that the sensory zone alone is involved in hysteria. There are other pathological processes in which the sympathetic or trophic nerves participate: in gangrene, due to contact with chemical agents such as phenol, which causes local abolition of sensation, as well as direct action on the vessels which are paralyzed, and their functions abolished. Cold, in the form of ether spray will arrest sensation, and if persisted in attack the vasomotor nerves of the vessels, causing gangrene.

While anesthesia of the sensory nerves alone is able to prevent or remove inflammation, the action is more prompt and powerful if the sympathetic fibres are also paralyzed, as has been shown in animal experiments by Samuel. Furthermore, everything published on Bier's stasis forces us to the conclusion that it is an excellent anesthetic. In fact, it would seem that the only conclusions to be arrived at is that the antiphlogistic value of Bier's method must be due alone to this property of anesthesia.

Rosenbach, elsewhere referred to, declares that the favorable action of anesthetics does not depend essentially upon the removal of pain; that pain is but one incident, however significant it may be considered, in a composite process. He believes that these remedies, local and general anesthetics, act directly upon the inflammed tissues themselves, *i.e.* upon the internal metabolism, their influence being of a tonic or regulating character. Heat, redness, and swelling all indicate a disordered internal working of the tissue cells. When it is not possible to cut short a mucous inflammation which has diffused beyond a certain point, with profuse secretion, for instance bronchitis, nothing relieves the condition so promptly or so well as repeated doses of an opiate, notably morphine, which influences the internal workings of the mucosa by arresting the secretory or motor spasm of the smallest elements of the hyperemia. The effect of this treatment is often astonishing; for with a single stroke the fluid secretion is checked and eventually removed.

Rosenbach prefers morphine to which he attributes a special action in restoring the normal activity of the tissues and in regulating their internal work, and especially because its effects are more prolonged than those of the local anesthetics proper. When the effects of the latter wear off, the hyperemia returns, so he claims. Nevertheless, in all local external inflammations Spiess's local method gives the best chance for rapid recovery; while in inflammations of the internal mucosa, especially in erysipelas under certain conditions, a general de-

pression of excitability offers greater advantages.

Rosenbach continues: "However much I agree with others as to the favorable effects of anesthetics and sleep, my explanation of such results differs essentially from that of Spiess, for while it cannot be denied that sleep eliminates reflex action and with it numerous phenomena which militate against healing, yet this salutary result is not due to loss of consciousness alone, for the inaction of the cerebral cortex is only an expression of diminished work of the organism as a whole." Rosenbach further believes that during sleep the anabolic activity of the tissues is increased so that only the gross impulses of sensations are abolished, the finer ones which preside over tissue changes being uninterrupted.

In regard to general narcotics, ether and chloroform work primarily upon the nerve contents, while morphine, although its action is eventually central, acts primarily upon the peripheral nerves.

Opium in the treatment of acute peritonitis has long been regarded as not only a panacea, but as a curative agent, and this through its action upon the nerves. It facilitates rest or sleep, which is all-important; favors localization of the morbid processes by suppressing peristaltic movements which would break adhesions. The objections to opium treatment of peritonitis are that it masks the clinical picture and that meteorism follows as does also constipation. If small doses, however, are used and continued, says Pel, control of peristalsis is effected and meteorism is avoided, while the inhibitory effect upon the nerves is in evidence.

In conclusion it would seem that, if irritation can be avoided, inflammation will not occur; and it would follow that this treatment should not be confined to merely local conditions, but should be extended to inflammations of deep seated structures as well. The nerve trunks supplying a number of organs or areas can, many of them, be reached by local anesthetics or by such narcotics as will control pain, thus influencing localized irritation, and so the damage to organs or tissues can be avoided. This opens up a wide field for experimentation with a prospect that success will follow. Surely earnest trials are to be recommended in view of the results above detailed.

OUR MEDICAL EDUCATIONAL SYSTEM.

By O. L. MULOT, M.D.,

BROOKLYN, N. Y.

For some time past there has been manifest a widespread interest in our general educational system, and the opinions of those, qualified by training and position, who have critically examined into these conditions, have made it clear that there is need for salutary changes and reforms. That special educational systems could not escape this general analysis is only natural and right, for in no class of schools is it more important that their product be the best. That medical graduates should be trained to the very highest possible practical and theoretical efficiency is of great importance to the general public and to our standing as a medically learned nation.

No schools in this country have undergone such changes and improvements as the medical colleges. The requisite time of study has been doubled and the number of studies in which the student is expected to qualify has been trebled; but with all this, when one follows even meager reports of the discussions and deliberations of the American Academy of Medicine it becomes evident that there has not been a general all-around improvement. A speaker, at a meeting of the American Academy of Medicine, held in Pittsburg, January 2 and 3, 1908,* quoting from a report of the Committee of "The National Confederation of State Medical Examining and Licensing Boards," showed the wide variance in time, devoted to various subjects in different schools; obstetrics ranging from 460 hours in one school to 52 hours in another, orthopedic surgery from 780 hours to 13 hours, general surgery from 2221 hours to 72 hours, physiology from 750 hours to 56 hours, chemistry from 756 hours to 78 hours. These grotesque figures demand that we pause, examine, and analyze them. They do not mean that all the low figures are in one school or all the high ones in another, and they can mean only one of two things. For instance in the case where only 52 hours are devoted to obstetrics, it probably means that there is no man in that faculty who is really fitted to properly teach that subject. Surely the subject is of such vast importance, no matter in what community a man goes to practise, that the graduate needs a better knowledge of it than could be obtained in that length of time; it would take a student longer than that to read a compend, to say nothing of manikin demonstrations, which in lieu of actual clinical experience is the next best thing and certainly superior to purely didactic teaching. Every community needs a better trained man in this branch.

On the other hand, in the school in which 780 hours or devoted to orthopedic surgery, we have in all probability, a strong, able, dominating personality, who demands, for what justly in the general makeup of a physician's knowledge must be considered a minor, time and a proficiency that the student must get at the expense of some other subject probably one of more general, all-around practical value. In the case where 2,221 hours are devoted to surgery, it means that at least one half if not more of the students' time is taken up by this one subject. It must follow that the other studies suffer, and the graduates from that school feel and are handicapped in a general practice, which is what most of them must go into.

If these deductions are correct, what, then, is the remedy? While there have been many papers and much discussion on this subject, these have lacked definite remedial plans. My only excuse for adding to this discussion is to point out lines along which salutory changes could be accomplished and urge the adoption of plans to bring about their realization. It would also seem common sense to devote effort first to the proper proportion and grouping of the subjects of the medical course, and have this definitely settled, before we indulge in talk about what studies the prospective medical student can advantageously take up during the last two years of his academic course.

The question of proper proportion and grouping of the subjects of the medical course could well be submitted to a convention to which all of the medical schools should be invited to send delegates. Here could be worked out a maximum and minimum schedule of hours for each subject, or group of subjects for each year, which would give the best all-around results and standards, not alone final but for each year of the course. That such taking of

*Medical Record, February 1, 1908.

council together of teachers could bring only gain to each school and each subject is certain, and inestimable advantages to the student body would grow from it. The possible good which can spring from this plan is far too great to warrant an off-hand rejection. It may be argued that some schools, and among these there might be large and small ones, would not participate. But were such a convention and its findings, which, of course, should be binding, to receive the endorsement of the medical examining and licensing boards, and these grant to the graduates of the schools signatory to the convention, a license to practise without further examination, it would force every school to become signatory and comply with its findings. Some may advance the objection that the examining and licensing boards would never do this, as it would practically be terminating their own existence. This does not necessarily follow, for in these boards could very well be placed the whole examining duties, not simply the finals but the year's end examinations. This I believe is practised in England; it would do away with touchstone subjects that have often driven worthy students from one school to another. These touchstone subjects have been the source of much of the contempt that the graduates of small schools have complained of and experienced at the hands of those from the larger and more pretentious ones. There has been much wrong in this: a subject should be made a touchstone only when it is very well taught, and this has not always been the case.

The harmonizing in all schools of the groups of studies for each year and the equalizing of standards would make it possible for the student to go from one school to another, taking a year here and a year there, without each time having to undergo the ordeal of extra examinations. It would do away with the superciliousness which the graduates from small schools have so often undeservedly experienced. This going from school to school is very common in Europe, particularly in Germany, and has much to recommend it. The student becomes familiar with the ideas of several teachers of the same subject, which in itself is of advantage in more ways than one. Should he desire, and opportunity offer, a teaching career, he is in a position to have inherited virtues from all of his teachers, enabling him better to recognize their defects and reject the latter, and hence is pedagogically more valuable to the school and his pupils. Furthermore, to many students this plan would offer economic advantages; he could take his first three years in the college or colleges nearest his home, perhaps in small cities where clinical material is not abundant and still in such schools be properly prepared to take his final year in one of the schools in a large city where there is a superabundance of clinical material. While the small college may object to such an arrangement, still it would be a perfectly dignified rôle to fill. The main object should not be the number of graduates, but well-taught students, and that will redound more to the credit of an institution than large classes. The railroad fare for a long trip to great centers of population and the much higher cost of living are economic factors that the student would, and the college should, consider; and other things being equal these should assure the school proper patronage from its legitimate territory.

This question of clinical material is an all important one to medical schools and their students. Just how large a number of inhabitants is necessary to give adequate material it is not intended here to go into; the schools are established, to move them to more advantageous centers, which would be the only remedy, is impracticable for several reasons. Often a school has been started in a city that affords ample material for one school, and then for reasons that we ignore, a second school is established, but the material that was adequate for one does not suffice for two, with the result that we have two schools that are suffering from this defect. This is a very common condition of affairs, and there are quite a few cities, that, according to post-office classification are second and third rate cities, in which are located three and four medical schools. The obvious remedy, consolidation, would bring prosperity to the school and fame as a medical educational center to the city. Furthermore, the adoption of this plan of harmonized and interscholastically standardized teaching and curricula would bring some changes in the number of graduates who make pilgrimages to European shrines of learning. Large numbers of men, from our different schools have gone abroad each year, from schools of such diverse standards, not so much diverse as a whole, but in individual subjects, men coming from schools in small centers where there is an admitted lack of clinical material. These men medically and often also linguistically unprepared have gone to study with men who are teaching advanced and complex work. This was a bad advertisement and has much to do with the poor opinion and esteem in which the product of our medical schools is held in Europe. The welcome which is accorded American dollars must not be misconstrued. This country of ours presents grand opportunities for clinical studies and of these more students should avail themselves, before going abroad.

But to return to the question where a school lacks a man or men to teach a certain subject, what is to be done? In the large schools there are to be found, in every department, promising men filling minor positions; among these may be found men who besides being thoroughly competent in their branch of medical science also possess in a high degree pedagogic talent, and the latter is a personal asset that does not or has not received sufficient consideration at the hands of medical school authorities. To such men a call to a professorship would mean a distinct step toward their goal. Yet many could not accept such a call even if made, unless there went with it an adequate compensation. A salary at least sufficient for immediate living expenses; few can afford to give up the private practice which they have built up, go to other fields, and begin again the tedious work of starting anew, even for the prestige of the title of professor. This is common practice abroad, particularly in Germany. There a man starts in as an instructor, I believe they there call it a "Privat dozent" and if he, to borrow a slang term, "makes good" he can at any time expect a call to a professorship in some other school. In that country progress in the career of a medical educator is not a question of sticking in one school and waiting until those above drop out either by death or resignation. There it is rare that a man has climbed the ladder to a professorship in the same school in which he started his career as a teacher. This plan of calling from one school to another has much to recommend it. The rubbing up against a different set of coworkers infuses new ideas and new methods into both sides and minimizes the retention of old grooves of thought and mannerism; this retention of mannerism is very

noticeable in our schools where it is the practice to develop from their own graduates their successions of teachers. Is this due to an intellectual heredity or is it just natural imitativeness?

Men who give their time to teaching medical students should be compensated, no matter what their position, from instructor up. If their services are good enough to accept, the services should be paid for, and if not good enough to be paid for, then their work is not good enough for the students. In divinity, law, and academic schools do men teach gratuitously? No, they are paid and paid well. There certainly is no reason why medical schools and medical teaching should be an exception. This is a deplorable and demoralizing state of affairs and leaves little attraction in a career as a medical educator, no matter how congenial such work might be to a man, or he by nature endowed with talent for the same. Then, too, when the college does compensate a man, the sum is so ridiculously small, that when mentioned to those in other walks of life, you are regarded as a man whose veracity is to be questioned; and when the hearers are assured that it is the truth, they ask, "Why do you do it?" Still it must be done and under existing circumstances some must make the sacrifice. But this does not make it right. "Well, why do you do it?" I wonder how many teachers of medicine have asked themselves that question over and over again. How many things do we doctors do, for which we get no compensation, though for similar work in other walks of life there is monetary reward.

It requires but little calculation to convince anyone that such a teacher's salary list could not be met from the sum of the fees received from the students; but do the fees received from the students in the divinity, law, and academic schools, suffice to meet the salary lists of those institutions? Evidently not; it must come from an endowed fund. You say, "Ah, there's the rub!" Medical schools are not being endowed as are other schools. Let us ask ourselves, in all candor, upon whom the responsibility for this condition should fall. Are not doctors, particularly those who stand high in the profession and practice among the rich, in just as good a position to obtain gifts and endowments for medical schools, as are ministers, lawyers, and the alumni of academic institutions? That they surely are, I think no one will dispute. What then will explain this indifference? Does the medical alumnus owe less fealty to his alma mater than is given to her of other schools? This can and should be remedied, but the big ones in the profession must make the beginning and then the lesser ones will not be found wanting. Is the proper education of medical men, the very best possible medical schools of less importance to the community, than are other branches? If this question is properly presented to those who can best answer, it will be satisfactorily met, as the Carnegie, Rockefeller, and Phipps donations prove.

On this question of fealty to our alma mater, I think I can do no better than to quote, in his own words, the sentiments of a recent graduate, on this point. "A student finds a big difference between academic and medical schools. In the former, the professors and instructors are ever ready and willing to explain and help him, and he goes to them with his perplexities without fear or trepidation. Not so in the latter; there a question is frowned at, illy explained, or ignored. If, in a medical school, a student fails in a study and he makes inquiry, he can get no satisfaction. Many of the minor instructors seem to consider their teaching duties a side issue. The student pays his fees and has a right to demand that the teaching be paramount not perfunctory. This cold, indifferent, often disdainful treatment that the student experiences from his medical teachers generates in his breast only a feeling of indifference for his alma mater."

This question of the attitude of teachers to students is a serious one, and should receive earnest attention from those in authority. It constitutes a most powerful argument for the plea of compensation of teachers. If their services were paid for, it would be an incentive to make their work interesting and valuable to the students. They would not consider their teaching duties as a side issue and the faculty would be in a better position to demand good work, also find it easier to satisfactorily fill vacancies. As things now stand there is too little incentive and the prospects of promotion are too poor to warrant a man to make such sacrifices of his private interests as a teaching career exacts. The raising of endowment funds for the compensation of teachers and the calling of men from one college to another would promptly work beneficent changes in this attitude of teachers toward students. There can be no elective studies in medicine during the pregraduating years, but where two men are teaching practically the same subject, I can see no objection and believe only good would come from allowing the student the choice with which of these he wishes to pursue the subject. On another occasion I have expressed the belief that the student body can safely be trusted to form a correct value of a teacher, and this matter of student choice, besides stimulating the natural pride of the instructor, would demonstrate, both to the faculty and the individual teacher, his pedagogic usefulness or uselessness, and thus materially aid in the elimination of dead wood from the teaching staff.

Medical science is undergoing constant changes, and as a result of this certain branches ascend or descend in the scale of relative importance, necessitating revisement and readjustment of schedules. The medical course should be well balanced, the relative and positive values of each subject well weighed, and the time allotment for each so adjusted as to produce a well-rounded whole. No subject, particularly not one of relatively minor importance, should be allowed time at the expense of another of more positive practical value. By a revisement of schedules and the introduction of better pedagogic methods it would be possible to effect economies of time and for the medical student that "time is money" is as true as for any other. I do not mean by that to shorten the course—far from it—but to gain time for other studies. Nor should one year's schedule be so crowded as to leave the student little or no time for text-book study or recreation, and another year's work so chopped up by hours of required attendance at the school that the intervening time is practically wasted. This can and should be avoided. The study week of 40 hours and the course of 40 weeks, permits of such arrangement as to avoid this. There should be no hesitancy in the adoption of better and more expeditious teaching methods. For example, in the teaching of anatomy, the student hears lectures on osteology, syndesmology, and so on; then he begins to dissect. In the lecture room he is taught anatomy from within out, and in the dissecting room he is taught it from without in, and the latter is the form in which he has the most need to know his anatomy. Then why

not entirely abolish the first method, do away with the lectures, take half of the time thus gained, add it to the second method, and the other half of the time thus saved devote to other studies? This certainly would be a time economy. For this plan, divide the class into three or four sections, according to the division of the cadaver, place an anatomist at the head of each section. Section "A" to dissect the head and neck; let the teacher explain the first dissection of these parts; how to dissect, for what to look, and where to find it. The next section proceeds in the same manner and each section continues this work until nothing but the separate bony component parts remain. Then the sections change their parts but not their teachers. Anatomy could thus be taught in three-fourths of the time and a better and more lasting knowledge of the subject instilled than is now done.

That certain subjects receive more time and attention than their ultimate usefulness to the graduate would warrant, I believe is true. I have especially in mind the work that the student is required to do with the microscope; histology, physiology, embryology, bacteriology, pathology, and clinical pathology. Far from deprecating the value of exact knowledge of tissues and disease processes, still this knowledge is of value only when it supplements other knowledge. Every one who has thoughtfully followed the progress of bacteriology must realize how this is lessening daily the value of microscopical pathology. We are fast coming to the understanding that all these cellular changes are, after all, only the immediate or remote results of bacterial action. For the men who intend to specialize along such lines, the present quantity of microscope work is a help, but these form after all only a very small percentage of each year's college output. Let the men who have been responsible for this forcing of microscopical study pause and think how small a percentage of the graduates start out equipped with a microscope. Such an equipment is so costly that few can afford it at the outset. There are so many more pressing demands upon the young student's purse—office furniture, instruments, larger works of reference for his library than sufficed for his college studies—that an outlay approximating $200 for a microscope and the necessary accessories, is not to be thought of until his earnings warrant it. In the meantime he has his necessary microscopical work done and done better than he himself could do it, by those who have specialized on this work, and done at a cost less than the interest would amount to on the sum involved, were he so to equip himself. During this time he is losing his microscopic technique. Not alone this, but from where is the general practitioner to get pathological material to continue his work? The law prohibits the physician from possessing parts of bodies, but even were this not so and he regard this law as a dead letter, he is prohibited from experimenting on living animals, and this certainly shuts him out from individual bacteriological work. Thus it happens that five years after graduation nine-tenths of the men look through a microscope with much less understanding than when they were students. They have fast lost something to the acquiring of which they were forced to devote much time, and the individual has learned that he can practise medicine without a microscope. His patients pay others for the necessary examinations, and had he made these himself he would have been refused compensation for this work by them, they considering such work when performed by the doctor whom they consult as something included in the fee.

As the course stands now every student feels that he must get a hospital appointment before entering private practice, and while this is of unquestionable desirability, still there are not enough hospitals to go around, and impecuniosity prevents some from taking a hospital service. Why should these be forced to go through their professional life feeling handicapped by a lack of hospital experience if the college really did the very best possible by them for the fees they paid?

Then, too, there are many hospitals in which an interne service can be of only questionable value. In many of these small hospitals the work is almost entirely surgical, and this not always of a very high order. The shameless bartering and wire pulling that has attended the naming of the visiting staff of some of our sectarian hospitals, where for a certain sum a man is made an attending, and for half such a sum he is made only an assisting attending, makes it easy to understand that the graduate may find himself in a hospital, with superiors who can teach him little, because these hold their positions for reasons other than merit. In just such hospitals it occurs that the interne positions are promised to this or that man, one or two years before his graduation, and the advertised competitive examination, to which the student body is invited, is a mere matter of form, a foregone conclusion, and a farce.

So many of our men have been abroad, but how little original work have we seen emanate from them since their return? We have permitted a detrimental Germano-mania to possess us in this matter of foreign study. What was earlier said about being linguistically illy prepared applies particularly here. German is a very difficult language for the English tongue, as there is almost no similarity between the two; but there is a great similarity between French and particularly medical French and medical English. How gross is the ignorance in our country of even the names of Frenchmen who have given to the world recent valuable discoveries, is shown by the fact that recently a lecturer, speaking of the agglutination test, said that it was discovered by a German by the name of Widal. His surprise was great when, after the lecture, I informed him that F. Widal is a professor of the Faculty of Medicine at Paris. Are we not as competent as our Teutonic colleagues to judge the claims of discoveries, or must these all first get the hallmark of Germany and come to us via that route? There is always some danger that in transit the name of the maker may be come illegally blurred. Is England in medical science to-day a negligible quantity? Their books would not warrant an affirmative reply to this question. Knowledge is not the exclusive property of any nation, race, or creed, and there can be no doubt that many of our leading men, and by that I mean especially those who are teaching, have been handicapped by a lack of knowledge of foreign languages; it is bad to be dependent upon translators who in turn are dependent upon publishers. The latter say the French authors are not in fashion now, and for this reason, and it is a perfectly good one from a business standpoint, translations of French works are not available. Personally familiar with both languages, I feel justified in saying that this is a great loss. The pendulum of popular favor is bound to swing back, and then we will have to guard against the other extreme.

We must not forget to make due allowance for the difference of conditions under which our teachers have to work in this country from those in Europe. Nevertheless too few of our leading men are original and independent investigators. The conditions which prevent them from being this are to be deplored, but those conditions which are mostly of a mercantile character should not be allowed to entirely choke scientific work, which always will yield more lasting honors. To illustrate: a student came to me and asked that I suggest a line for original research; he had asked the director of the pathological laboratory and several others, teachers in the school that he was attending, and none could or seemed willing to indicate a line for him to work on. This is a strange and sad state of affairs. With so many questions waiting to be solved and for the solution of which the profession is anxiously waiting, should the help of any worker be discouraged? It is difficult under such circumstances not to form too hasty and harsh judgment. These men may have lacked faith in the ability of that student to undertake such work, and have suspected that the scholarship and its advantages, rather than an earnest desire for, and a love of, research were the mainsprings of his ambition.

If our medical schools were brought up to a higher efficiency and more systematized courses given, there is no reason why the schools should not enjoy the lucrative patronage of those seeking postgraduate instruction. The very existence of postgraduate schools is the best evidence that the regular schools are not what they should or could be. I do not mean by that that if our schools were raised even to ideal heights and standards that men would not feel the need and desire for postgraduate work: far from it; but these men should find such work in its best and highest form in the regular schools and under the teachers there. Besides, it has been a business shortsightedness to allow the fees that have been paid into postgraduate schools to flow elsewhere than into the treasury of the regular schools. Such fees would have gone a long way towards the compensation of teachers. Whether the suggestions for a conference or convention, for uniformity of curricula and standards, and the creation of funds to salary teachers are adopted or not, should in no way interfere or even delay the institution of such improvements as it lies in the power of the teaching body of each school to make, for which, from a study of a large number of announcements, there seems need in every school. The teaching bodies should not wait until the now only isolated grumblings from students* swell to an angry, turbulent protest that will drag the family skeleton of medical educational institutions from its dark closet and parade it through the sensational lay papers, to the delectation of Christian scientists, faith curists, and others.

424 Halsey Street.

Nervous Exhaustion and Lecithin.—F. W. Alexander recommends the use of lecithin in neurasthenia. He says that "the nerve centers depend on lecithin for the highest performance of their functions, and must obtain it from the lecithin extracted from the food eaten. Brain and nerve exhaustion are caused through the undue expenditure of lecithin in the brain." This loss "is eliminated by the administration of lecithin or organic phosphorus. Lecithin should be considered as a food rather than a drug." —*The Medical Times*, London.

*Medical Record, Jan. 4. 1908.

A CLINICAL AND BACTERIOLOGICAL STUDY OF FORTY-ONE CONSECUTIVE CASES OF DIPHTHERIA.

By E. E. WUTTKE, M.D.,

HALSTEAD, KANSAS.

Diphtheria is a disease which most commonly affects the posterior portions of the buccal cavity, producing, as the name implies, in its so-called typical form, a pseudomembrane which covers a part or whole of the tonsils and adjacent structures. On the other hand, in some instances as my cases lead me particularly to emphasize, there may be only a simple redness and swelling of the tonsils and pharyngeal wall without membrane. This absence of membrane in true diphtheria has been noted by many observers, beginning with Trousseau[1] in 1828, reiterated with more accurate data by Gerhardt[2] in 1883, and by many others since, but has not received sufficient attention from writers of books and practising physicians.

The clinical manifestations of diphtheria are so divergent that no one can diagnose correctly on clinical grounds alone any but the typical cases. The assistance of bacteriological analysis is necessary before the identity of the less typical examples, and particularly those without membrane, can be proved, therefore, bacteriological methods should always be employed in cases of nose and throat lesions during the occurrence of epidemics, whether a membrane is present or not. The time, skill, and apparatus required are insignificant compared to the value of the accurate data thus acquired.

The prominent clinical phenomena noted in my cases were as follows: The majority of patients, as is characteristic of the disease, were dull, listless, lethargic, that is, asthenia was marked. In some of the milder cases and others seen near the onset this feature was not present. In the cases due to the Klebs-Loeffler bacillus alone, severe pain was not present. Only in those cases complicated by a secondary infection by the ordinary pus cocci was severe pain a prominent feature.

An erythematous eruption resembling that of measles was noted in one case without membrane and in one case with a typical membrane. In two cases without membrane the eruption simulated that of scarlet fever very closely. In the three cases without membrane this eruption was misleading and could not have been diagnosed without bacteriological examination.

In those cases due to the bacillus of diphtheria alone the temperature noted ran from 97 to 102, 99 and 99½ was noted in very many cases for several days. In those cases associated with the staphylococcus and streptococcus and adenitis the temperature was irregular, running from 98 to 104, up one day and down again, then up again.

The pulse rates noted ran from 100 to 160; 120 to 140 being the most frequent. In one case due to the Klebs-Loeffler bacillus alone the pulse was maintained at 160 for three successive days.

Cervical lymphadenitis presenting on inspection a mass as large as half of a hen's egg and larger was present in ten of the cases without membrane. In two of these it was bilateral, extremely painful, tender, and the skin a bright red in color. In one case suppuration necessitated surgical treatment. The abscess contained staphylococci and streptococci but no bacilli. Nine cases of typical diphtheria with membrane also showed a pronounced adenitis.

In one of these the swelling involved the region from the parotid gland above to the clavicle below, and from the median line in front to the median line behind. Staphylococci were found in the throat cultures of all cases in which adenitis occurred.

A history of frequent colds and preexisting chronic tonsillitis was noted in a majority of all cases. To establish the importance of these conditions as predisposing factors the following experiments were made: A culture was made from a normal adult throat as a control. This culture was incubated at body temperature for 24 hours, when it showed a scanty growth consisting of streptococci and staphylococci. A fresh subculture of *B. diphtheriæ* from case 22 was rubbed thoroughly over the tonsils. A culture was then taken every 24 hours for a period of two weeks. These cultures all showed a few typical Klebs-Loeffler bacilli, increasing in number for the first three days then slowly decreasing and disappearing in two weeks. A very marked increase in number of the staphylococci and streptococci as compared with the control was noted in all these cultures. Redness of the pharynx was present for a week. No other local or general symptoms were ever noted.

The same experiment was made using a pure culture purchased from a manufacturing chemist, resulting in fewer bacilli in the cultures and less reaction. In the next experiment a half dozen superficial incisions were made on the tonsils with a scapel and a 24-hour culture from case 40 was rubbed into these incisions by means of a platinum wire. The results were identical with those described above. No general symptoms of any kind arose in any of these experiments. An incision through the skin covering the deltoid was made with a scalpel and a swab direct from the throat of case 40 was rubbed into the wound. This procedure was repeated twice using a twenty-four-hour culture from the same throat (case 40). Case 40 had a mild attack of scarlet fever seven weeks before and was examined bacteriologically at that time. Strictly local lesions of an intense character were produced. Forty-eight hours after inoculation for a radius of 1 cm. there was an areola with a sharply defined border, intensely red, slightly elevated. In its center there was a small necrotic focus containing a yellowish-white exudate consisting of diphtheria bacilli, fibrin, leucocytes, and fixed cells, which are cells in an advanced state of degeneration. Cultures on blood serum developed only Klebs-Loeffler bacilli identical with those in the original culture. The same experiment was repeated with bacilli from case 41 with the same results. The results of these experiments indicate: 1, that the Klebs-Loeffler bacilli stimulate the growth of the normal bacterial inhabitants of the throat probably by preparing a favorable soil. 2. That the normal human throat offers considerable resistance to *B. diphtheriæ*, successfully withstanding large numbers of them, even when the mucous membrane is broken.

Pathological anatomy and pathogenesis of pseudomembrane. The essentials of the local lesions are degenerative changes in the epithelial cells with an abundant fibrinous exudate. There is a multiplication of the nuclei by direct division into two to ten. Vacuolation of the cytoplasm, necrosis of the cell, fragmentation of the nuclei, or hyaline transformation.

The inflammatory exudate collects in the cytoplasm of degenerating epithelial cells causing vacuolation, or it may accumulate below the cornified layer of squamous epithelium. The cellular elements are polynuclear endothelial cells and to a less extent those of a lymphoid type: to this we must add a supply of fibrin deposited in the epithelial cells and between the individual cells.

The membrane depends on the distribution of this fibrin, degenerative and exudative processes separately or combined (due to toxic action). In the beginning the blood-vessels are engorged and the lymph vessels dilated. General edema of the tissues with a diffuse formation of fibrin in the field.

Diphtheria without Membrane.—In my 28 cases of diphtheria without membrane the local lesions consisted of more or less but never extreme swelling. Edema or submucous effusion rendering the tissues translucent was never present. There was a bright uniform redness of the tonsils, pillars, soft palate, and post pharyngeal wall. No dilated blood-vessels were visible as in acute pharyngitis.

Councilman, Mallory, and Pearce[3] studied 251 fatal cases of diphtheria autopsies in the Boston City Hospital from Jan. 1, 1891 to June 30, 1905. They found a definite membrane in 148 or not quite 60 per cent (58.9%) of fatal cases. On the other hand, there are frequently non-diphtheritic lesions associated with a pseudomembraneous condition of the mouth and larynx.

Koplik,[4] working in the Carnegie Laboratory, made a very exhaustive study of a series of cases in which he noted some true diphtherias which never manifested any pseudomembranes, only redness and swelling. The most of these were mild but others were fatal. At the same time he found many cases with a typical pseudomembrane which showed only streptococci or the pseudodiphtheria bacillus of Hofmann.

Parke & Beebe[5] (1895), relate the following case: "A child with chronic coryza and anemia was admitted to a hospital ward. Five days later four of his neighbors developed diphtheria, two of them were fatal. Diphtheria bacilli were found in his nasal discharge."

Newsholme[6] (1904), reported the case of a boy who complained of headache followed by a nasal discharge. In a few days three of his classmates died of diphtheria. His nose was then examined and diphtheria bacilli were found. He also relates concerning another child who was ill for one day with sore throat and a headache. Five days later his sister developed diphtheria. A swab from his throat demonstrated diphtheria bacilli.

Bissel (1902), relates a case of a child who had a mild sore throat some time previously. Diphtheria occurred in the household he visited. Berry (1900), gives a number of similar cases.

Many observers have confirmed the fact that forms of diphtheria exist which clinically run their course without the manifestation of any visible membrane, from which at any time in the course of the disease the Klebs-Loeffler bacilli can be isolated.

From the literature and from my own cases it is safe to conclude that these so-called atypical cases are not rare and are frequently overlooked, and are the foci for the spread of the disease. The fact should be emphasized that the pseudomembrane is not a reliable diagnostic feature. We should amend our clinical conception of diphtheria to include all cases which when examined bacteriologically are shown to be due to the Klebs-Loeffler bacillus.

Membranes Not Diphtheritic.—Prudden[7] found twenty-two fatal cases of membraneous inflammation of the mouth and throat due only to the strepto-

coccus. Woodhead[7] (1901), found streptococci to be the only organism present in 565 out of 1,960 of 28 per cent of cases diagnosed on clinical grounds as diphtheria. Staphylococci alone sometimes cause a membrane and inflammation, but the mixed infection with the streptococci and staphylococci is the most common cause of non-diphtheritic membrane; 985, or 50 per cent of Woodhead's 1,960, were such.

Pneumococci may form a membrane in the throat as in a case reported by Cary and Lyon[8] in which a lobar pneumonia was complicated by a pesudomembrane, on nearly every mucous surface of the body, including conjunctiva, anus, and glans penis. Pneumococci only were found in all lesions. Also Netter (1891), when urgent symptoms required tracheotomy. The membrane expelled contained only pneumococci.

In Woodhead's series, 50 per cent of the pseudomembranes were due to the streptococci and staphylococci mixed and 28 per cent were due to the streptococci alone. While in Councilman, Mallory, and Pearce's series a definite membrane was present only in 60 per cent of fatal diphtheria.

The bacteriological identification of my cases was made by cultural characteristics and morphology. A few animal inoculations were made use of. Neisser's stain, Loeffler's alkaline methylene blue, and Cobbett's method of mounting in staining fluid and decolorizing with acetic acid while under observation were used in all cases. All measurements given were made on mounts in Canada balsam. Loeffler's blood serum, hydrocele fluid, and glucose agar were used as culture media. The culture tubes were inoculated at the bedside by means of a sterile platinum wire or a sterile cotton swab, and immediately attached to my undershirt by means of a string or adhesive plaster. When incubated in this way the growth of the diphtheria bacillus is astonishingly rapid and luxuriant. Colonies can be seen with the naked eye after four and a half hours and we never failed to obtain an abundant growth in less than twelve hours. The advantages of incubating this way are: 1. Much time is saved as incubation begins when the patient is first seen. 2. The culture positively cannot become too hot or too cold. 3. It is unnecessary to make a special trip to the laboratory to place the tube in an incubator. 4. The growth can be watched while attending to the usual duties.

Diphtheria with Membrane.—Oct. 16, 1908. Case I. Male, age 8, gave a history of an indefinite illness for a number of days. T. 101°. P. 128. Moderate cervical adenitis, throat red and swollen, small patches of whitish membrane not unlike that in follicular tonsillitis on the right tonsil. A spread made from a swab showed many bacilli of an average length of three microns. They were irregular in contour and stained irregularly. A culture made on blood serum showed an abundant growth in fifteen hours, consisting of small colonies, grayish white in color with a slightly yellowish tinge and a moist, greasy surface. A stained spread from this fifteen-hour culture consisted mainly of bacilli of an average length of 3 microns and about 0.5 micron wide. Grouping was characteristic. There were numerous granules or polar bodies by Neisser's stain.

Oct. 17, gave 4,000 units of antitoxin. Oct. 18, membrane all gone, feels better. Oct. 22, T. normal, P. 80 to 100, irregular and weak. Slight paralysis of the soft palate. Slowly regained perfect health.

Diphtheria without Membrane.—Case 22, Nov. 14, 1908. R. S., male, age 2, sick for five days. Bilateral swelling below angles of lower jaw, most pronounced on left. Pharynx red and swollen, left tonsil swollen more than the right. T. 100°., P. 140. Twenty-hour blood serum culture was composed of a few staphylococci and many bacilli ½ micron wide and 1½ microns long on an average, many were only 1 micron long and the longest measured 3 microns. Grouping, staining, and polar bodies were absolutely characteristic. Nov. 21, T. 103° in groin. P. 140; entire throat red and swollen; no exudate or membrane. Nov. 22, T. 96.8° in groin. P. 140. Dec. 5, large fluctuating tumor left side of the neck; two free incisions were made. Twenty-hour blood serum culture consisted mostly of staphylococci and a few streptococci. No bacilli of any kind were found in the abscess. December 10, healing nicely by granulation.

Diphtheria with membrane following scarlet fever. Case 40. March 3, 1909. E. McF., male, age 7. Had a mild attack of scarlet fever Feb. 1, 1909. Examined bacteriologically, found only streptococci and staphylococci. Complete recovery without complications. March 3, 1909, feeling badly two days. T. 103°. P. 148. General redness of pharynx, yellowish-white patch on the upper border of the right tonsil. Four thousand units of antitoxin were given and a culture was made. March 4, feeling as well as usual, running around eating apples T. 98.8°. P. 128. Throat red, only a small shred of membrane left. March 6, a membrane on the other tonsil. No treatment given. March 7, all membrane gone. Twelve-hour blood serum culture was pure Klebs-Loeffler bacilli from 1 to 3 microns long on an average, the most of them being 1.5 micron.

Summary of the forty-one cases may be made as follows:

Thirteen cases had a typical pseudomembrane. The bacilli were longer than in the non-membraneous, averaging 3 microns on the twenty-four hour cultures, they ran a more severe course and were frequently followed by paralyses.

Twenty-eight cases never exhibited membrane at any time. The bacilli in these non-membraneous cases were smaller than those in the cases with membrane, running from 1 to 3 microns, most of them being about 1.5 microns long. These cases ran a milder course throughout, responded readily and in a characteristic manner to treatment by antitoxin, none developed paralysis. It would seem that in these cases the bacilli belonging to the short variety were not so virulent as the longer forms in the cases with membrane. One case followed a peritonsillar abscess after its spontaneous rupture. Two cases followed scarlet fever, with an interval of perfect health of four and seven weeks, respectively. One case was followed by an abscess due to staphylococci and streptococci which was treated surgically. Paralytic sequelæ were noted in five cases. In three of these there was a myocarditis.

Antitoxin in doses of 4,000 units was administered to all cases as early as possible. In two advanced cases this dose was repeated twice. Recovery was complete and prompt in all cases. No local treatment was used in any case. Prophylactic doses of 1,000 units each were given to fifty-four individuals who had been exposed. None of these developed the disease. The only undesirable effect of the serum noted was an urticarial eruption in about 20 per cent of all cases, but most frequently in

those cases where only 1,000 units had been administered.

COMPILATION OF SOME FACTS CONCERNING HIGH-FREQUENCY CURRENTS.

By W. PARKER WORSTER, A.M., M.D.,

NEW YORK.

High-frequency currents are currents of very high potential, having oscillations running up into the millions per second. This frequency of oscillation is obtained by passing a current of electricity through a series of step-up transformers and condensers and spark gaps and Tesla coils, in such a manner as to raise the potential, causing Hersian waves to emanate from the circuit, which are of as high tension as the high-frequency apparatus itself and creating differences of potential in the windings of the coil. The action of the current upon the primary or core is to magnetize and demagnetize the core, creating lines of force which circulate around the secondary winding, causing induced currents in the latter, which are of very high tension; those passing to the condensers hasten the elimination of the current from the primary at a tremendous speed; for the efficiency of the coil is dependent upon the rapidity with which the elimination takes place. A coil that is wound both in its primary and secondary to a very large size gives the greatest length and thickness of spark; the coil giving the thickest fuzzy spark stream is the best for most efficient results. The interrupted induction coil gives the best results for therapeutic work.

Vibratory electrization produces internal respiration of the tissues of the body, and by its dilating properties upon the arterioles hastens the flow of nutritive blood into the capillaries and thence to the tissues, forming the metabolic processes and placing the patient in a better condition for a longer and more active life. One should insulate the patient to get the normal value of high frequency. Currents of high frequency registering from 300 to 800 milliampères can be passed through the body without causing the least sensation or bodily inconvenience, which characteristic distinguishes high frequency from all other forms of electrical energy. High-frequency currents have a great influence upon respiration. They deepen the inspiration at once, and cause the patient to breathe freer, although this evidence is not always manifest to the same extent in all cases submitted for treatment, increasing the oxygen consumed from 6 to 19 per cent and hastening the activity of the reduction of oxyhemoglobin in cases of poor nutrition.

I know of no remedial agent that will eradicate pain so quickly, effectively, and permanently as the high-frequency current in the form of the transresonator effleuve in cases of muscular rheumatism in any part of the body, neuritis, articular rheumatism, and chronic rheumatism. It is the treatment par excellence, the pain being cured and muscular activity restored in a few treatments.

In neuritis sciatica, lumbago, and especially gout, the pain disappears as if by magic. One should begin with a mild current and increase its strength a little each treatment. In arthritis deformans, with pain, stiffness, tendernesss, and swelling not only in the joints but in the shaft of the bones between the joints, the pain, soreness, and stiffness disappear rapidly, no matter how long they may have existed, and even the deformities of the joints take on a more natural condition and straighten to a great extent.

In cases of submetabolism, where the urine shows a low specific gravity and the excretion of urea about half normal, where the resistance is subnormal, from whatever cause, which cases if let alone would develop Bright's disease or diabetes, nothing will raise the metabolism so quickly as the D'Arsonval current of from 300 to 400 milliampères for five minutes, followed by the effleuve for five minutes daily, or every other day as the case may be. This raises the specific gravity of the urine from a dangerous low to a higher one, and the patient from a condition of submetabolism to one of activity and life. In one of my cases, the specific gravity of the urine was raised from 1005, with albumin, to 1028, no albumin, in fourteen treatments. But it has been my experience that in beginning general D'Arsonvalization, it is well always to give one or two treatments of transresonator effleuve at first, because the general D'Arsonvalization is apt to affect the patient badly and excite reactive effects, one of which, in the writer's experience, is a shaking and trembling for two or three days.

While undergoing treatment, the patient should always sleep in a well-ventilated room with windows open top and bottom, winter or summer, so that the full benefit of the fresh air can be obtained; for the deepening of the respiration produced at once by the current causes the patient to inhale more oxygen, which makes a great difference in the final result. One should exercise strenuously in the open air, increasing the walking distance with precision up to ten miles daily if possible. He should bathe every morning in a quick short bath of one and a half minutes' duration (not a cleansing bath) immediately on rising from bed, standing or sitting in about twelve inches of water at 100°, and washing down the body, chest, arms to elbows and back quickly with a coarse linen towel wet with water at 70° or lower (low enough to produce a gasp according to the patient's reactive capacity), and rubbing and slapping the body hard with the thoroughly wet towel four or five times all over (the towel must be linen), and then dress, go out, and exercise.

For the eradication and total destruction of warts, moles, naevi, excrescences, and small tumors, there is nothing so quickly and certainly effective, in my experience as the high-frequency metallic

discharge. For these purposes, I use a specially constructed electrode, made of glass 8 inches long, with a fine copper wire extending the whole length and ending flush with the glass in a small hole, the other end connected with the secondary of the Tesla coil, this being completely insulated so as to treat only the special spot desired and not any of the adjacent surface. With two and a half ampères of current, I have removed tumors as large as a small hickory nut without a particle of pain or a moment's detention of the patient from his usual avocation.

Many skin diseases yield very readily to the transresonator effleuve with two and a half ampères of current. One case of ringworm extending almost around the body was cured in ten treatments by the writer. A second case of ringworm with thick crusts of chronic eczema an eighth of an inch high, on the left gluteal region, the ringworm extending down between the buttocks upon the scrotum, was cured in twenty-eight treatments, leaving only the reddened spots, which are gradually disappearing, to tell the tale where the disease had existed.

High-frequency currents are to be used as a rule where the condition has existed for some time, say at least two months. Although in several cases of acute muscular rheumatism I have obtained most excellent quick results, generally speaking, the best results are obtained "not in the presence of acute disease" (Piffard). Old ulcers which have become indolent, some of twenty years' standing, can be healed up by the effleuve.

Several cases of rheumatoid arthritis combined with gout were relieved in from twelve to fifteen treatments each, not continuous but at sometimes long intervals, and my case-book contains many reports of cases in which free stimulation by drugs had been made to no purpose, but which yielded readily and promptly to high-frequency curents.

Finally, it is necessary that a careful diagnosis of the patient's physical condition be made in each individual case, for, in badly selected cases, the application of a high-frequency current produces not only an injurious effect upon the sensibility and condition of the patient, but also injures its reputation as a therapeutic agent.

Maritime Exchange Building, 78 and 80 Broad Street.

REPORT OF A CASE OF HEMORRHAGIC RENAL INFARCT.

By FORBES R. McCREERY, M.D.,

NEW YORK.

In the *Archives of Internal Medicine* for April, 1908, there is an article on the clinical manifestations of hemorrhagic renal infarct in which the author, Geo. Halperin, M.D., states that he has been able to find in literature reports of only ten cases in addition to his own. I am able to report another case.

E. M., aet 30, born in Ireland, single, a parlor maid, had been in my care for two years suffering from aortic incompetency. On repeated examinations the urine usually contained a trace of albumin and an occasional hyalin cast. Specific gravity, 1020 to 1032; urates and uric acid; otherwise normal. During the winter of 1905-6 she suffered from digestive disturbances suggestive at times of a peptic ulcer.

On April 23, 1906, after lavage, which relieved her gastric symptoms, patient was suddenly attacked by severe right-sided abnormal pain. I found the right kidney displaced forward and downward, movable, very tender, and possibly enlarged. Pulse, 60; urine acid, 1030; considerable albumin urates, a few epithelial casts, numerous renal and pelvic epithelia, no blood.

On April 26 her temperature rose to 102.6°. On the following day the amount of urine passed was 40 ounces. A few red cells were found.

April 29, urine, neutral 1014; trace of albumin; a few hyalin, and one epithelial cast, a very few red cells and epithelia as before; amount, 40 ounces. Temperature, normal.

May 8, urine acid, 1014; albumin trace, indican trace, microscopic, normal.

May 18, acid, 1028; albumin trace, blood, a few casts.

June 12, acid, 1022; albumin faint trace, a very few hyalin casts; uric acid crystals; no blood; no indican.

June 23, the patient went home to Ireland, where she died a few months later.

I considered this case at the time one of embolism of a main branch of the right renal artery. I considered but ruled out calculus and Dietl's crises. I have no recollection of previous knowledge that the patient had a moveable right kidney, probably because I had never had occasion to examine her for one, my attention being usually centered on her heart. I did not report the case before, for the reason that, until seeing Dr. Halperin's article, I did not know that it was one of especial interest to others than myself.

123 East Fortieth Street.

Insufficiency of the Suprarenals in Scarlatina.—V. Hutinel describes symptoms arising in the course of scarlatina which are very suggestive of insufficiency of the suprarenals, and gives a most interesting illustrative case. The symptoms are asthenia, depression, failure of the heart power, hypotension of the arteries, tendency to syncope, abdominal pains, and a brown coloration of the skin. The use of small doses of adrenalin had a remarkable effect in the cases cited, the patient recovering after being in an apparently desperate condition. From the literature of past times the author drawn descriptions of similar cases accurately described and observed, but with etiology unknown. These seemed to indicate some kind of poisoning of the entire system. These symptoms are referable to the perversion of the function of the suprarenal capsules. In some cases autopsy shows changes in these organs, while in others that do not come to autopsy the syndrome is observed.—*Le Bulletin Médical.*

Contribution to the Therapeutics of Rupture of the Uterus or Vaginal Fornices.—Romolo Costa gives nine cases of rupture of the uterus and fornices treated by himself, and discusses the treatment of this condition. It occurs especially after version or forceps, when the physician does not realize the stretching of the lower uterine segment by the shoulders. Termination of labor by craniotomy, embryotomy, or evisceration, under anesthesia, are prophylactic operations. The serious factors in uterine rupture are hemorrhage, shock, and sepsis. Death rarely occurs from hemorrhage or shock—more often from sepsis due to blood and other fluids and solids which escape into the abdomen. Hemorrhage is serious when arterial, which is the case when with a contracted uterus we have continuous and violent hemorrhage. Here the uterine artery is lacerated in the parametrium, and an immediate laparotomy by the abdomen is indicated. The vaginal route is slower and gives poorer access to the wound. Venous hemorrhage may be controlled by an aseptic tampon. In slight lacerations it may be possible to suture the wound, especially when the peritoreal cavity has not been entered. In severe cases a tampon may be introduced temporarily at the home of the patient, and she may be removed to a hospital. The tampon is then removed, an accurate diagnosis made, and operation performed. To prevent sepsis, drainage must be established by means of gauze; antiseptic injections must be confined to the vagina, and all possible clots and other débris removed from the uterus. If operation becomes necessary the abdominal route is best; the wound may be sutured, the uterus amputated, or total hysterectomy performed, according to the demands of the case.—*Annali di Ostetricia e Ginecologia.*

THE BACTERIOLOGY AND PATHOLOGICAL ANATOMY OF LEPROSY.

THE researches of the past twelve years, since the first Lepra Congress, have firmly established the lepra bacillus of Hansen as the specific cause of leprosy. Special staining methods have been introduced by which it is possible to demonstrate the young homogeneous bacilli, the old, granular, and dead bacilli, the resistant fat in the bacilli, and the fat in the glœa which holds them together. By these methods it has been shown that a large number of the bacilli in the tissues are dead. The differentiation by means of staining methods of the lepra bacillus from the tubercle bacillus is, however, still uncertain, and the classification of the lepra bacillus is also under discussion. J. M. H. MacLeod, writing on this subject in *The Lancet* of August 21, says that this bacillus was formerly believed to belong to the class of *Schizomycetes,* but the finding of a cladothrix arrangement and of branching forms like actinomyces has rendered it probable that it belongs to the class of the *Streptotrichœ.* Numerous attempts have been made to cultivate the bacillus, but no medium has been discovered on which it will invariably grow, and it has not been proved that the bacillus is present and can lead a saprophytic existence on decayed organic matter. Until this is proved the theory that the disease may result from the eating of decayed fish, pork, etc., cannot be accepted. Numerous inoculation experiments have been made, but up to the present time no lower animal has been found which is susceptible to leprosy, neither has the microbe been found in insects suspected of disseminating the disease. All attempts to extract from lepromata a substance which would produce in leprous patients a reaction analogous to that produced by tuberculin in tuberculous patients have been unsuccessful. It seems probable that the most common mode of invasion is *via* the nasal mucosa and upper respiratory passages, although it is possible that invasion may take place through the skin and the genital organs. Congenital leprosy has not been proved to occur.

The lepra bacilli may occur in the skin, eyes, mucous membranes, lymphatic glands, viscera, and peripheral nerves. They do not occur in physiological secretions unless pathologically contaminated. According as the bacilli show a special predilection for the peripheral nerves in contradistinction to a more general invasion of the tissues, with the formation of nodules or lepromata in the skin and viscera, so two types of disease are produced, the maculo-anesthetic and the nodular type. Various hypotheses have been advanced as to the precise conditions which determine whether a case should pertain to one or the other type, but thus far, MacLeod says, nothing definite can be stated. After gaining entrance into a tissue the bacilli appear to lie at first in the lymph spaces, and produce by their presence a mild inflammatory reaction. At first the infiltration is non-distinctive and consists of round spindle-shaped connective-tissue cells, lymphocytes, mast cells, and occasional polynuclear leucocytes should pyogenic organisms be present. So far the situation of the bacilli is mainly extracellular. As the bacilli multiply they form colonies united by homogeneous zooglœa, and the infiltration begins to show the presence of plasma cells around the capillaries. A certain number of bacilli become intracellular and large characteristic cells, containing vacuoles, one or more badly stained nuclei and bacilli singly or in clumps may be noted. These are the so-called lepra cells, on the origin of which there has been much diversity of opinion. The bacilli enter and spread slowly through the lymphatics, forming new leprous deposits wherever they go, or they are more quickly distributed to neighboring and distant parts by the blood stream. In the skin lepromata, bacilli have been confined as a rule to the corium, and there is generally a thin layer which is free from bacilli immediately beneath the epidermis. The fact, however, which appears to have been quite certainly determined, that bacilli have been found on the surface of the epidermis and in the scales is important as affecting the spread of the disease.

With regard to the leprous changes in the viscera, little has been added to our knowledge in recent years. The changes in the blood-vessels are now well known; the blood changes, however, have not been sufficiently worked out. Considerable advance has been made in regard to our knowledge of leprosy of the eyes. This is one of the late manifestations of nodular leprosy, and occurs usually after the face, eyebrows, and eyelids have been affected, being rarely a primary manifestation. Observers differ in opinion with regard to the histopathology of the patches of maculo-anesthetic leprosy, the chief point at issue being in regard to the manner in which these changes are brought about. As to nerve leprosy, all leprologists are agreed that the lepra bacilli may affect the nerves in their whole course, but there is no unanimity with regard to the mode of invasion, and opinions are divided as to whether the nerve infections occur first in the finer endings in the skin and ascend or whether there is a descending process, the result of general infection. There is great diversity of opinion also in regard to the presence of lepra bacilli in the cord and spinal ganglia. Until most or all of these problems are solved, it is not probable that any great advance will be made in the direction of a specific therapy of the disease, or of a certain means of prophylaxis, though, in northern latitudes, at least, the disease, possibly because of hygienic betterments, seems to be in a process of gradual extinction.

THE THERAPEUTIC VALUE OF ANTI-DIPHTHERITIC SERUM AS EXPRESSED IN UNITS OF ANTITOXINS.

Practice in the manufacture and therapeutic use of diphtheria antitoxin is to-day almost universally based on the theory that the curative value of any particular serum is accurately measured by its potency as expressed in units of antitoxin. Following the classical work of Ehrlich in the course of which the present system of standardizing the serum was developed, his pupils did careful work in which this was shown to be true so far as the experimental intoxication of guinea-pigs and rabbits with diphtheria toxin was concerned.

It is obviously impossible to obtain reliable data on this important question by direct comparison of various sera in the treatment of the human disease. Moreover, the disease cannot be reproduced in animals by infecting with the diphtheria bacillus apart from its toxin. The only reliable evidence obtainable, therefore, is to be derived from work with the toxin as a disease-producing agent. The French scientists, following Roux, have never fully accepted the view that the antitoxin unit was a true measure of the curative value of the serum, but they did not at first back this opinion with satisfactory experimental work, and the question was generally regarded as settled. In 1905, however, Cruveilhier reported experiments which seemed to show some discrepancy between the strength of the serum as expressed in units and its curative value against the intoxication. The report reopened the question and led to a thorough reexamination of the whole matter. Steinhardt and Banzhof in the Research Laboratory of the New York City Board of Health made experiments which resulted in accordance with those of the Ehrlich school. Belfanti came to the same conclusion. Kraus and Schwoner, on the other hand, seemed to obtain evidence of a striking sort in favor of the view of Roux and Cruveilhier. The established reputation of Kraus as an active investigator in the field of immunity, the detail with which the work was presented, and the striking discrepancy between the neutralizing and curative values of the antitoxin combined to make this a most serious attack on the view of Ehrlich.

A more recent, and, on the whole, the most convincing contribution to this subject is now presented by Berghaus of Ehrlich's Laboratory in Frankfort, in a series of articles in the *Centralblatt für Bakteriologie*, vols. 48, 49, and 50. He reports the examination from this point of view of a number of sera collected from the serum laboratories in various parts of the world. Among these were the particular preparations used by Kraus and Schwoner as a basis for their work. Berghaus' results are entirely in favor of the original opinion of Ehrlich. Kraus' results are shown to be viciated by serious and fundamental errors. Three samples of serum, used by him and asserted to have a potency in antitoxin units of 180 to 200 units per cubic centimeter, were found by Berghaus to have an actual potency of 300, 400, and 600 units respectively. These sera might obviously give a curative value out of all proportion to the neutralizing value as represented by the figures of Kraus. The experimental methods of Kraus and Schwoner are also shown to be not those best designed for an accurate estimation of the curative value of the serum. Correcting the error of titration and adopting somewhat different methods for the estimation of the curative value of the serum, Berghaus found that for these sera of Kraus, as well as for all others he examined, the potency of the serum expressed in standard units of antitoxin represented accurately its therapeutic value when injected as a curative agent some time after the injection of the toxin.

The reply of Kraus to this report (*Zeitschrift für Immunitätsfrage*, Bd. 2, S. 723) is a defensive argument in favor of his methods and interpretation, but bringing out few new facts. The discussion will no doubt be continued with vigor. In the meantime there is no good reason to fear that present practice is based on a faulty foundation.

Prevention of Epidemic Cerebrospinal Meningitis.

With more accurate knowledge of the cause and mode of infection of cerebrospinal meningitis we are able to undertake more effective methods of prophylaxis. Under the old theory of conveyance of the germs by means of the clothing of those who attend the sick from contagious diseases and by the furniture used in the sick-room, the disinfection of the room and of the bedding used by the patient has been relied upon to prevent the spread of the disease. The researches of the last quarter of a century into the causes of contagious disease, however, bid fair to revolutionize the methods of prophylaxis. It is now believed that the secretions from the nasopharynx of the patient and of those who surround him convey the germs. As in the case of typhoid fever, so in that of cerebrospinal meningitis, there are persons who, though entirely well themselves, are carrying about with them the germs of the disease. In an article in *l'Echo Médical du Nord*, for July 25, 1909, G. Petit says that the nasopharyngeal catarrh is the primary affection, the meningeal involvement being only a secondary manifestation. The isolation of the patient is as important as ever, as is also the immediate destruction of all materials that have been contaminated with the discharges from mouth and nose. Aside from such measures the disinfection of the room and bedding is of secondary importance. Petit describes an epidemic of cerebrospinal meningitis which occurred in the Pas-de-Calais, including in all twenty-six cases. He gives conclusive evidence of the carrying of germs in the throats of well persons who had been in contact with the sick, and the spread of the epidemic to distant towns by this means. At the outset of the epidemic the government offered to furnish antimeningococcic serum for free use in stopping the epidemic, and the serum was used in twenty-one of the cases affected. The mortality was much less among patients who received injections than among those not treated in this way. It is not necessary in most cases to give more than two injections, but it is of the greatest importance that the injections should be made very early in the disease, as soon as a troubled cerebrospinal fluid is detected by lumbar puncture, without waiting for a bacteriological diagnosis. The serum should be used in all sporadic cases, and thus we may prevent

the disease from reaching the epidemic stage. Every person who can possibly carry the germs about as a result of being in contact with the patient should be kept under observation for at least three weeks, and the secretions examined daily. Those caring for the sick should frequently disinfect the nose, mouth, and throat, and should take the greatest care to avoid the possibility of drop infection. These measures carefully carried out have proved of the greatest possible value in limiting meningitis in the French army, and the successful results which have been seen to follow their observance have gone very far to lessen the terrors of this still most formidable disease.

Intravenous Injections of Chloroform.

The recent advances in our knowledge of the practical use of anesthetics have been great, especially those steps leading toward the elimination as far as possible of the element of asphyxiation from general narcosis. New masks have been invented and various means of administering oxygen with the anesthetic have been devised, some of them of such complexity that it is almost requisite for an anesthetist to be an expert engineer. Now, however, Burkhardt of Würzburg, in an article in the *Münchener medizinische Wochenschrift* for August 17, 1909, suggests that we should do away with all these apparatuses and cease giving anesthetics by inhalation at all, resorting to what he seems to regard as the simple alternative of administering chloroform intravenously. He has experimented on a series of animals and on four human beings with results which he claims indicate that the intravenous injection of chloroform is an agreeable and a safe method of narcosis. His method consists in the slow injection into the veins of a solution of 0.63 c.c. of chloroform in 100 c.c. of physiological saline solution. When stronger solutions than these were used the chloroform did not dissolve, and the droplets getting into the circulation were liable to cause dangerous symptoms. In animals it was found that a quantity of chloroform equivalent to 0.041 per cent. of the blood was required to produce complete anesthesia. Much more than this had to be given, however, as much of the drug was lost through the lungs before reaching the general circulation. In the case of the four human beings on whom the method was used the amount of the chloroform-saline solution injected varied between 950 c.c. and and 1,950 c.c., according to the duration of the operation. The onset of the anesthesia was somewhat slower than when chloroform was given by inhalation, but the recovery was much more rapid and there was a remarkable freedom from untoward symptoms. Headache and vomiting but rarely occurred during recovery. The author emphasizes the two facts that this method is especially convenient during operations on the head or mouth, and that by it the anesthetist is able to tell the exact amount of the drug which reaches the circulation, which is certainly an advantage in the use of any drug. The occurrence, however, in two of his four cases of hemoglobinuria, the great danger to the heart of an overdose of chloroform, and the general tendency to abandon this substance as far as possible for safer anesthetics would suggest that this method of producing general anesthesia, simple and comfortable as it may seem to its author to be, will probably not be received with widespread enthusiasm.

Animal Membrane in Joint Surgery.

During the past few years various orthopedic surgeons have been working on the problem of plastic surgery of ankylosed joints, especially in an effort to obtain a method of interposing some material between the surfaces of the bone which will prevent reuniting after the joints have been separated by operative procedures. For this purpose many different materials have been used. Sections of skin have been turned in and inserted between the roughened ends of the bone. Flaps of muscle have been used by Quenn, Nélaton, Murphy, Hoffa, and others. Chumsky, disappointed with these organic materials, essayed to insert nonabsorbable substances, as zinc, rubber, celluloid, silver, and celloidin, but with no permanent results. Decalcified bone, ivory, and magnesium were better but far from satisfactory. Again, fascia and peritoneum of animals have been tried with but indifferent outcome. In the *Johns Hopkins Hospital Bulletin* for September, Baer proposes a new substance for joint covering. He says that the material to procure success must be of small bulk, and must be absorbable. It must, however, be but very slowly absorbed, for it is the rapid disappearance of Cargile membrane that constitutes its main drawback. After studying various animal membranes, Baer has decided that that which best fits his purpose is pig's bladder. This, when properly chromicized, will remain intact for forty days. In his report he cites three cases of ankylosis in which Cargile membrane was used without results and five in which the chromicized pig's bladder was inserted. In these latter cases permanent motion remained in each case. One case of tuberculous ankylosis of the hip showed, after eight months, thirty-five degrees of motion, and another, after five months, fifty degrees; one synostosis of the elbow, in which primary insertion of Cargile membrane had failed, gave a final rotation of 110° after the use of the pig's bladder; while two knee joints, one gonorrheal and one tuberculous, gave 35° and 75°, respectively. The report is given as preliminary and merely to suggest the method. The results, however, are distinctly good so far, and the method would appear to be deserving of further trial in more extended material.

News of the Week.

Typhoid Fever in New York City.—In connection with the recent reports of the prevalence of typhoid fever in New York, the statement is made to the effect that the city as a whole has less typhoid than usual at this time of the year. At the end of last week there were in all, according to the Board of Health reports, 230 cases of the disease in the city, whereas the records for this season during the past four years show that in 1908 there were 309 cases, in 1907 371 cases, in 1906 307 cases, and in 1905 243 cases. The epidemic reported last week is localized to a few blocks near the river in the upper East Side, and it seems not improbable that the condition of the bathing places along the East River piers may be responsible for this local prevalence. A city sewer empties into the East River at the end of every street hereabouts. The autumn increase in typhoid fever throughout the city is largely due to imported cases coming home from vacations. A filtration plant is, however, needed in New York, and it is probable the disease will never be stamped out until this has been obtained.

Investigating the Origin of Typhoid Fever.—The Health Board of Chicago has been investigating the cause of typhoid fever reported to the Department. Of 43 patients whose dietary habits were inquired into last week, it was found that 13 had been using pasteurized milk; 14 raw milk, and two both pasteurized and raw milk. In the remaining cases no definite information could be obtained. Eight of the patients had been eating at restaurants and five had been out of the city within two weeks previous to being taken ill.

Cholera in Antwerp.—It was officially reported last week that there were three cases of Asiatic cholera in Antwerp last week with one fatality.

Wholesale Ptomain Poisoning.—Fifty men who attended a banquet at Barberton, O., on September 9, were made seriously ill, probably by the oysters or lobsters served at the dinner. Among the sufferers were six physicians.

The Legal Status of Osteopathic Practitioners.—A decision was handed down recently by Supreme Court Justice Crane of Brooklyn denying to the Society of Osteopathists the injunction for which they applied to prevent the Board of Health from enforcing the new section of the Sanitary Code which prevents the issuing of transit permits for the removal or burial of dead bodies except on the certificate of a physician holding the degree of doctor of medicine. The new section was promulgated after the courts had decided against the Board of Health on the question of receiving death certificates from osteopathists. The judge in his decision said that whereas under the old code which provided that any attending physician might sign death certificates, osteopathists, being considered as physicians under the law, might do so. However, as the new sanitary code specified that the certificates must be signed by a physician holding the degree of doctor of medicine, osteopathists did not come within the law. He further decided that the Board of Health was acting within its rights in restricting the issuing of burial permits only on the certificates of holders of the degree of doctor of medicine, and that the new section of the sanitary code must be considered to be legal. According to this osteopathists may sign death certificates, but no body may be removed or buried unless a physician also certifies to the death or the coroner is consulted.

Kentucky State University Medical School.—A committee of physicians of Lexington, Ky., held a meeting recently at which a plan was formulated for the establishment of a medical college as an adjunct to Kentucky State University. The college will be established and will be opened for matriculates early this fall. The plan agreed on provides that the board of trustees is to have full control of the new medical school. The first two years of the course will be taught at Lexington and the last two years at Louisville.

Tent Colony in Peoria.—A tent colony is being planned for Peoria, Ill., to be put in operation in Old Prospect Park by October 1. After the first six months it is expected that the institution will be self-supporting.

The Protestant Hospital of Columbus, O., has purchased the building of the Parkview Sanitarium on North Park street, Columbus. The building will be converted into a new nurses' home for the hospital.

New Hospital at Lachine, P. Q.—The first General Hospital to be established in the Province of Quebec under the management of the Victorian Order of Nurses was opened at Lachine a few days ago.

Hospital Benefactions.—In honor of his recent marriage, Mr. James N. Jarvie of Montclair, N. J., made several donations to charitable institutions. Among these the Mountainside Hospital of Montclair and the Job Harris Home for the Aged each receive $26,000. One hundred and fifty thousand dollars has been bequeather to the Dixon Public Hospital Illinois, by the will of the late Judge Solomon H. Bethea, on condition that the name of the hospital be changed to the Katherine Shaw Bethea Hospital.

The Western Association for the Preservation of Medical Records was organized in May, 1909, for the purpose of collecting the historical and biographical records of the profession of the West and South. The members desire to preserve anything and everything pertaining to Western medicine and medical men, and are anxious to enlist the active help and support of every member of the profession who is in sympathy with their aims. There are no membership fees or obligations of any kind. Arrangements have been made with the Lloyd Library, Cincinnati, O., for the proper housing of the material collected. The latter will be systematically arranged, catalogued, and properly preserved so that it can be made available for research work. The association is particularly anxious to obtain (1) medical journals published in the West prior to 1880; (2) medical books and pamphlets written or published in the West; (3) manuscripts and autographs of early Western physicians; (4) old diplomas and other documents of a medical character; (5) proceedings of medical societies; (6) reports of hospitals and other medical institutions; (7) catalogues and announcements of Western medical colleges of all "schools"; (8) biographies and portraits of Western physicians; (9) information and material of any kind pertaining to medicine and medical men and affairs in the West; (10) curios of a medico-historical character. All contributions should be sent in care of the librarian, and in view of the fact that the Association is performing a labor of love and has no funds, all contributions sent by express or freight should be prepaid so that no expense may accrue to the Association. The necessary expenses of the Association are at present being met by voluntary contributions of its organizers. The officers of the association are Drs. C. A. L. Reed, *chairman;* Otto Juettner, *secretary;* A. G. Drury, 710 W. Eighth street, Cincinnati, O., *librarian.*

The American Association of Obstetricians and Gynecologists will hold its twenty-second annual meeting at Fort Wayne, Ind., on September 21, 22, and 23, 1909. The president of the association is Dr. William Henry Humiston of Cleveland and the secretary Dr. William Warren Potter of Buffalo. The annual dinner will be held on Wednesday evening, September 22, and members intending to attend this are requested to notify the chairman of the committee on arrangements, Dr. Miles F. Porter, 207 West Wayne street, Fort Wayne, Ind.

The Pecas Valley Medical Society was organized recently at Roswell, N. M., to cover the counties of Chaves, Eddy, and Roosevelt. The follow-

ing officers were elected: *President,* Dr. J. E. Caldwell of Hagerman; *Vice-president,* Dr. O. H. Haymaker of Roswell; *Secretary* and *Treasurer,* Dr. Frederick J. Walter of Roswell; *Councillors,* Dr. D. N. Galloway of Roswell, Dr. Frederick F. Doepp of Carlsbad, and Dr. W. W. Phillips of Roswell.

Women's Medical Association of Wisconsin.—At a meeting held recently in Oshkosh, Wis., a new society was organized among the women physicians of Wisconsin for the purpose of mutual improvement, harmony, and social intercourse among the women doctors of Wisconsin. The following officers were elected: *President,* Dr. Adeline Riddle of Oshkosh; *Vice-president,* Dr. Anna B. Coor of Juneau; *Secretary,* Dr. Minnie M. Hopkins of Oconto; *Treasurer,* Dr. Hanna M. Droppers of Milwaukee; *Board of Preventive Medicine,* Dr. Julia Riddle of Oshkosh, *chairman; Board of Censors,* Dr. Luella Axtell of Marinette, Dr. Belle Painter Nair of Port Washington, and Dr. Ella Chaffee-Fay of Whitewater. The next annual meeting will be held in Milwaukee in September, 1910.

Medical Men at the Pole.—Dr. Frederick A. Cook, who claims to have reached the North Pole a year in advance of Peary, is of German descent but was born in Sullivan County, N. Y. He was graduated from the New York University Medical School in 1890 and has since practised in Brooklyn in the intervals of serving on or leading exploring expeditions. His first trip to the cold regions was as surgeon to a Peary expedition in 1891, and subsequently he went as surgeon with the Belgian Antarctic expedition. Dr. John W. Goodsell, the surgeon of the Peary expedition, is a native of Pennsylvania and a graduate of the Pulte (Homeopathic) Medical College of Cincinnati in 1898.

Dr. W. S. Howell of Winnebago has been appointed local surgeon for the Northwestern Railroad System.

Obituary Notes.—Dr. Henry Cadwalader Chapman of Philadelphia died at his summer home at Bar Harbor on September 8, at the age of 65 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1867, subsequently serving as resident physician in the Pennsylvania Hospital. After spending several years abroad he became demonstrator of anatomy and physiology in the University of Pennsylvania. In 1877 he became lecturer on comparative anatomy and general physiology in the Jefferson Medical College and two years later he was elected professor of the institutes of medicine and of medical jurisprudence. The University of Pennsylvania conferred on him the degree of Doctor of Science at its last commencement. He was one of the founders of the Zoological Society of Philadelphia, chairman of the Board of Curators of the Academy of the Natural Sciences from 1891 to 1904, member of the American Physiological Society, College of Physicians of Philadelphia. He was a voluminous writer and was the author of a text-book on physiology and another on medical jurisprudence.

Dr. James Greer Stanton of Milford, Del., died on September 4 as the result of taking a wrong dose of medicine, aged 49 years. He was a graduate of the Jefferson Medical College in 1884. He was a member of the Kent County Medical Society and the Delaware State Medical Society. He was a colonel on the staff of Gov. Lea from 1905 until last January. He was twice Mayor of Milford and was president of the Board of Health for several years.

Dr. Hugh T. Adams of Jersey City died September 8, 1909, at his home as the result of a railroad accident, at the age of 63 years. Dr. Adams was a native of Ireland and a graduate of Queen's College, Dublin, in 1869.

Dr. George M. Angell of Atlanta, Ill., died at his home September 5, 1909, in the ninetieth year of his age. Dr. Angell was a graduate of the Harvard Medical School in 1847 and is said to have been present at the first operation performed under ether anesthesia in Boston. For over fifty years Dr. Angell has practised in Atlanta.

Dr. Charles A. Ball of Washington, D. C., died at his home on September 3, 1909, aged 58 years. Dr. Ball was a graduate of the Medical Department of Columbian College in 1877 and had practised medicine in Washington for thirty years. He was a member of the Medical Association of the District of Columbia and the American Medical Association.

Dr. James Brown Burnet of Newark, N. J., died at his home September 7, 1909, aged 67 years. He was a graduate of New York University Medical College in 1866, and a former house physician of Bellevue Hospital.

Dr. William T. Griffith of Washington, Ill., died at his home on September 2, 1909, at the age of 76 years. He had practised medicine in Washington for forty-six years and was at one time coroner of Tazewell County.

Dr. Albert B. Henderson, late of the United States Army, died at Denver, Col., August 28, 1909, of tuberculosis, aged 32 years. Dr. Henderson was a graduate of the Detroit Medical College in 1899. On graduation he enlisted as hospital steward in the Thirty-first Michigan Volunteers. In 1900 he joined the regular army as assistant surgeon and lieutenant and served in the Philippines. It was while serving in the Philippines that Dr. Henderson contracted the disease which caused his death.

Dr. Thomas V. Parker of Los Angeles, Cal., died in that city on August 31, 1909, aged 41 years. He had served for the past twelve years as surgeon at the Soldiers' Home.

Dr. Carl M. Sederblom of Milwaukee died on August 18, 1909, at a hotel in Helsingfors, Finland. For many years Dr. Sederblom had practised in Milwaukee, but had left a few months ago for Finland in the hopes of regaining his failing health.

Dr. Edwin M. Shaw of Cameron, Texas, died at the Milam Hospital, August 31, 1909, at the age of 49 years. He was a graduate of the Atlanta Medical College in 1884, and a member of the Milam County Medical Society and the State Medical Society of Texas. He served as regimental surgeon in the Spanish-American War and in the Texas State Militia.

Radium in Carcinoma of the Breast. Louis Wickham of the Radium Institute in Paris concluded a lecture in London by saying "that radium therapy is of service in the treatment of certain neoplasms of the breast in different ways: (1) Radium may cause a carcinoma of the breast to regress so as to give the appearance of a cure. (2) It may render operable a cancer otherwise inoperable. (3) It may act favorably on cases in which recurrence has taken place after the operation. (4) It may act on the surrounding infected glands. (5) In desperate cases it may relieve pain and diminish for a time the hemorrhage and the secretion from the ulcerated portion, and so prolong life. (6) It may be utilized after operation as a preventive means against return of the disease."—*Proceedings of the Royal Society of Medicine.*

Correspondence.

THE NEW LAW REGARDING THE LOCATION OF TUBERCULOSIS SANATORIA.

To the Editor of the Medical Record:

Sir:—In 1903 there was a law placed upon the statute books in this State which required the consent of the Town Board and of the County Supervisors before an institution for the care of the tuberculous could be located in any part of the State. The effect of this law was to delay for years the erection of a sanatorium by this city and to prevent the carrying out of any charitable sanatorium enterprise in the State. Of my knowledge, having originated an undertaking to care for the sufferers from pulmonary tuberculosis, of moderate means, in Brooklyn and Long Island, I can state that, although application was made to every township in Suffolk County, comprising almost the entire island, every one refused. In the township of Brookhaven, in which the Brooklyn Central Labor Union raised funds and purchased a tract of sixty-five acres for the purpose of the enterprise in question, known as the Long Island Open-Air Sanatorium, the Town Board's consent was first obtained, but the County Supervisors had yet to be dealt with, and before they could be induced to act favorably the Town Board, on a technicality, and as a result of popular agitation, rescinded their resolution, and thus absolutely stopped the enterprise. This occurred in 1906, and, as it was recognized that nothing further could be done unless the law was either repealed or modified, every effort was directed to effect this purpose. I understand, through the combined efforts of the many interested, Governor Hughes was induced to recommend in his last annual message the repeal or modification of this statute. As a consequence a bill was introduced in both houses and became a law on April 10 last. This bill provided that the State Commissioner of Health and the Health Officer of any township in which it was proposed to locate such an institution should constitute a board to consider the question. Should they be unable to agree, an appeal might be taken to another board, consisting of the Commissioner of Health, the Lieutenant Governor, and the Speaker of the Assembly, whose determination should be final.

The first application under this law was made by the Central Labor Union for permission to establish an institution, and public hearing was held in Patchogue on June 11 last. Although there was considerable local opposition, none of the virulence of three years ago was manifested, perhaps, as some of the town folks said, because many of the opponents recognized its futility, the final result of which was the granting of the application by the State Health Commissioner and local Health Officer. The locality selected is ideal, being about the geographical center of Long Island, and is sufficiently elevated to be reached by all cooling breezes in summer. The land is rolling in character and is well wooded, something unusual upon the island. While chiefly engineered by the Brooklyn Central Labor Union, all the labor organizations of the Greater City are expected to participate in the enterprise and to contribute funds for the buildings and equipment, although assistance from philanthropic individuals will also be sought. The amount desired is about $50,000, but failure to raise this sum will only necessitate a smaller beginning and will not defeat the undertaking. Plans at present intend a two-story central administration building with wings extending east and west for men and women, respectively. The wings are to be faced by verandas and backed by corridors, and will provide altogether 100 single rooms of 1,500 cubic feet air space each. The building is to be of wood, covered with cement, and of hardwood and plaster interiorly, with cement floorings.

Admission to the institution will be given to all persons of small means in need of such care from the Greater City and Long Island, at a charge varying with whatever the cost of maintenance may prove to be, as it is only desired to make it self-supporting. Owing to the slowness with which the required money can be raised, it will probably be a year or so yet before patients can be received.

As the opening wedge has thus been driven, it is earnestly hoped that other labor organizations, charitable societies, and philanthropically inclined individuals will provide throughout the State wherever needed such local sanatoria, which are in line with the most practical antituberculosis work, as sanatorium treatment is undoubtedly the most efficacious method of treating the disease. As it is known that no climate is either specific or even necessary for its treatment, and as the disease is practically so universal, almost every county might with advantage have such an institution. Furthermore, when a sufferer recovers his health in his own climate, with no assistance except from rest, food, and air, he is convinced that his future prospects are good, provided the new habits inculcated are not forgotten. Horace Greeley, M.D.

Pacific and Clinton Streets, Brooklyn, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

AFRICAN ENTOMOLOGICAL RESEARCH—BIRTH RATES AND CIVILIZATION—SANITATION *VS.* SANATORIA—A PLAGUE EPIDEMIC—DENTAL CONGRESS—OBITUARY.

London, August 27, 1909.

The medical event this week is the appointment by the Colonial Office of an African entomological research committee, which, so far as can be ascertained, is received with gratification by those able to estimate its importance Both our schools of tropical medicine are represented on this committee. So are the universities, the British Museum, the Royal Society, and other bodies. It is intended to dispatch a trained entomologist to the east side of tropical Africa and another to the west to stimulate officials and other residents to collect and observe noxious insects and give instruction in scientific methods. It is hoped the committee will gain from them specimens and observations to be classified and distributed to institutions for instruction, and the committee will keep in touch with such work in Egypt, the Soudan, and South Africa. A bulletin is also suggested. By what seems a happy coincidence Sir Alfred Jones announces that the Liverpool Tropical School is going to establish a branch in the Canary Islands under the direction of Ronald Ross and Rubert Boyce. Sir Alfred means to equip the branch in a thoroughly efficient manner so that patients may be treated there and research carried on. The Grand Canary is a delightful climate for invalids to rest on their way home. Dr. Parsons, who has had experience in the East and in the Persian Gulf, will go out to take charge, and if the work grows will be reinforced.

The quarterly return of the Registrar-General, issued last week, shows that the birth rate in the second quarter of this year is the lowest recorded since the establishment of registration. This fact has again started a discussion on the danger of the continued fall and whether it is possible to arrest it. One school of sociologists have reckoned that at the present rate the population will become stationary in another twelve years, the annual increase having fallen already to only a little over 400,000. They predict the decay of the nation and profess to discern the commencement of the process in spread of artificial restraints to reproduction. The predominance of small families is put forth as a proof that the decline of the Empire has begun in the same way as in France, and that the Germans, already more numerous, will by their still continuing increase take the dominion of the world. In opposition, other sociologists maintain that the masses of the people do not attempt to limit their families, and that the evil of doing so is restricted to the wealthy, not a few of whom are more unfit for marriage than not as a consequence of luxury and debilitating causes in their previous generations.

Another view of the matter is that the retrograde movement of populations has always followed their advances, and that in obedience to a natural law. This view was held by Prof. Ludwig Gumphowicz, whose death on the 22d inst. is reported from Vienna. Probably the last article he wrote was on this subject for a French paper, in which he regrets wounding the susceptibilities of the readers, but says the first duty of science is the recognition of truth. He says, though a State is not a plant or animal, it is none the less a social formation subject to the same laws according to which it grows, produces a culture, wanes, and disappears. Europeans imagine their States must last; but that only shows their naïveté, for they must pass away like those of old. The symptoms of decadence are a high civilization and lowering birth rate. The higher the culture the greater the decline of birth rate and the nearer the end: the lower the civilization the higher

the birth rate and the greater the future, *i.e.* the life expectation of the State. This, he says, is a law to be stated by sociologists, but they do not pretend to explain it or modify the laws of nature. But, he adds, the realist sociologists have a potent salve for the fear of the French, and I suppose of the English, too. They may be reassured about the Germans, for the Slavs of Eastern Europe have a still higher natality. It was a natural instinct which allied the country with the lowest birth rate to that which has the highest. France may last for centuries, in spite of her low birth rate, while the high rate of Russia is an anxiety for Germany. Perhaps the professor would have added, had he survived, that our sociologists might take comfort in the *entente* with Russia and a hope of prolonged European equilibrium.

The open air treatment of consumption has occupied so large a field that in the opinion of some there is a danger of other measures being quite thrust out. And yet some of these are of supreme importance, and even if subsidiary must be regarded as the necessary basis. The present state of the City of Liverpool, contrasted with its condition fifty years ago, as recorded by a royal commission, presents a striking illustration of the effect upon tuberculosis of measures of general sanitation. The comparison was used by Dr. Hope, the City Medical Officer of Health, at the Tuberculosis Conference at Stockholm last month. He showed that the sanitary reforms introduced from time to time had been followed step by step by a decline in the mortality. The sanitation of the homes, the schools, the business premises, the provision of open spaces to widen streets, the baths, the improved water supply, all these, he said, had played their part. Millions had been expended on such works, but no one familiar with the sanitation of cities could suggest that equal results could have been obtained by the expenditure of the money on hospitals and sanitoria if the breeding places of tubercle had been left untouched. Voluntary notification of pauper consumptives had been replaced with advantage to a compulsory plan, but isolation accommodation for advanced cases was needed in the interest of the patients, their friends, and the public. The prospects of recovery, as well as the prevention of infection, were facilitated by removal to more suitable surroundings. The limitation of sanatorium treatment to carefully selected cases which were most likely to end in recovery ought not to be regarded as any limitation of the usefulness of isolation. On the contrary, good as it was for the patient, it was of less immediate value from the point of view of prevention than was the isolation of the advanced case, much as would be the restriction of hospital treatment to mild cases of scarlet fever to the rejection of the severe ones. In any case where the home surroundings, the habits, or other circumstances rendered a patient a danger to the public, Dr. Hope held that the interests of all would best be served by isolation.

The report of the Colonial Office on last year's epidemic of plague in West Africa shows the happy results of grappling with the disease by skilled sanitarians. Prof. J. W. Simpson undertook the work, and soon succeeded in controlling the outbreak, although the condition of the colony as regards sanitation was exceedingly unsatisfactory. In and around Accra there were 344 cases in the half year from January to July, and of these 300 were fatal. Professor Simpson made a tour through the colony after the epidemic, and is unable to find any redeeming feature as to the neglect of the public health, which seems to be universal. A strong sanitary policy is urgently needed, for no effort to cope with malarial disease or the conditions producing it has been made, although the natives have always suffered from what ought to be largely prevented, and these natives seem to have no prejudice against scientific efforts at prevention, for we are told that 35,000 of them willingly underwent preventive inoculation. The success reported will probably have a most beneficial effect on the native mind as to other sanitary measures. Only four of those who were inoculated took the disease, and one of these four recovered. A departmental committee to inquire into the sanitary state of the colony has reported further on the requirements, and it is hoped that action will not be delayed.

More than fifty delegates went from the United Kingdom to the International Dentists' Congress, which was opened at Berlin on Monday in the Reichstag Building. An extensive exhibition is connected with the congress, and the large collection, I hear, attracted much attention. The German Emperor sent copies of ancient dental instruments dating back to the early Christian era. The English association show a collection of charts for use in schools under the charge of the London County Council. The first day was occupied with formal business and receiving the delegates. On Tuesday morning the twelve sections set to work reading and discussing the papers, three of which were presented by British members. Later the visitors attended the celebration of the fiftieth anniversary of the German association, and in the evening a banquet was held. The British and Colonial delegates on Wednesday hoped for an early meeting in London.

By the death of Dr. Henry Radcliffe Crocker, a distinguished exponent of dermatology has passed away. He died suddenly in Switzerland on the 22d inst. while taking his holiday. He qualified in 1873, became M.D., London, in 1875, and was elected F.R.C.P. in 1887. As physician to the skin department at University College he had great opportunities of observation, and as lecturer of teaching. These he utilized fully and contributed much to the literature of the specialty. You will know his "Atlas," which appeared in 1893-'96, as well as his "Treatise." He wrote various articles in the Twentieth Century Practice, Heath's Dictionary, Allbutt's System, the Medico-Chirurgical Transactions, etc.

Dr. Theodore Davis, M.D., London F.R.C.S., who died on the 11th inst., aged seventy-five, passed his professional life at Clevedon, where his father practised before him, the two having together practised in the same place for eighty years. The late gentleman was a student of Birmingham, and afterward at St. Bartholomew's Hospital. He took the M.B. and F.R.C.S. in 1859 and proceeded to the M.D. in 1861. He was for many years surgeon to the local hospital and connected with various philanthropic societies.

Mr. Robert Gorton Coombe, F.R.C.S., has died in his ninety-second year. He took the M.R.C.S. in 1841, and was elected to the Fellowship in 1884.

The death is also reported of Dr. Deeping, J.P., who, after active practice in Essex for about thirty years, retired to Hastings, where he took a prominent part in public affairs and became president of the local conservative association. He qualified at the two London colleges in 1871-'72.

An inquest was held on the body of Fred. Taylor, a retired practitioner, aged seventy-eight, who was found on the 20th inst. dead at the roadside near his bicycle, and wearing his "cycloplane," an invention he had made for lessening the rider's weight on the machine, and with which he had often experimented. A verdict of natural death was returned.

Another doctor's sudden death necessitated an inquest. Dr. Mennie, aged thirty-one, after a hard day's work in the recent hot weather and a dose of chloral, which he had been taking for a few nights. Dr. Trevon found extensive disease of the heart at the post mortem, which, he said, would render the ordinary dose and the fatigue dangerous.

OUR VIENNA LETTER.

(From Our Regular Correspondent.)

SALICYLATES IN SPUTUM DIAGNOSIS—METABOLISM WITH EXTIRPATION OF THE LIVER—TREATMENT OF MORPHINISM BY SCOPOLAMINE-DIONINE—CAPACITY OF THE STOMACH AND GASTRIC TONE.

VIENNA, August 29, 1909.

FRITZ FALK and Fritz Tedesko have recently brought out the results of a new investigation in diagnosis from sputum examination. The method consists of giving the patient sodium salicylate in wafers by mouth, and examining the sputum twelve to fifteen hours later for salicylic acid. They have shown by a large series of cases that in acute or chronic, purulent, or congestive bronchitides and in bronchiectasis the sputum contains no salicylic acid, whereas in pneumonia the salicylic acid reaction is strongly positive. It was further shown that the intensity of the reaction runs parallel to the course of the disease. On recovery from the pneumonia the reaction disappears. This salicylic acid test is also regularly positive in the sputum of tuberculous patients, but many times weaker than in cases of pneumonia. The reaction is in general definitely stronger in acute cases of tuberculosis than in chronic ones.

Professor von Noorden has been able to show in a study of the migration of various substances into the

exudates that salicylic acid taken *per os* is excreted in large amounts into the joints.

Oskar Porges has carried out some interesting researches which give information as to the oxidation processes after extirpation of the liver. Animals were used in which ligation had been made of the abdominal aorta, the inferior vena cava, above the entrance of the hepatic vein, and the portal vein, so that the abdominal organs were removed *en masse* from the circulation. In such animals the expired air was examined according to the method of Zuntz. The expired air in each case was collected for over an hour, so as to equalize irregularities of respiration. In hungry animals a respiratory quotient of from 0.9 to 1.0 was found, pointing to a burning of carbohydrates in the muscles. Several control animals, which were treated in exactly similar manner, except for the ligatures of the vessels, gave respiratory quotients of 0.7. If one concludes from the experimental results that sugar is the exclusive source of muscular power, one must acknowledge that albumen and fat are changed into sugar before they can be utilized in the muscle. The organ which carries on this work may be the liver. According to the studies of Embden, the liver is also the place where fatty acids are transformed into the acetone bodies. In connection with these investigations we must consider the acetone bodies as intermediate products of the formation of sugar from fats, or at least from fatty acids. Porges was able to determine a new fact, namely, that in solutions of diacetic acid salts there occurred a substance which reduced Fehling's solution but gave no other carbohydrate reaction. Furthermore, Porges, in connection with Privatdozent Salomon, has carried out a liver extirpation experiment on a dog with pancreatic diabetes, and has found a respiratory quotient of 1.0. This finding would suggest that in diabetes the catabolism of sugar is not disturbed.

Professor Schlesinger has made some successful cures of the morphine habit by means of scopolamine dionine. He has noted for some time that in patients who receive morphine for pain the morphine doses can be made much smaller if scopolamine and dionine are added, and still a greater quieting effect is produced. He has now made use of this fact for the treatment of the morphine habit with excellent results. The time required for the withdrawal of the morphine is much shorter, and abstinence symptoms are lacking. In a case of morphine and cocaine habit, with a daily dose of 0.5 gm. morphine and 0.1 gm. cocaine the withdrawal was accomplished in fifteen days, and a few days later the scopolamine and dionine were discontinued. At first relatively large amounts of scopolamine and dionine were given. On the first day two to four injections were given of a solution consisting of 0.2 morphine, 0.00025 scopolamine, 0.3 dionine, and 10 c.c. water, and on the following days the number of injections, and especially the amount of morphine, were very rapidly reduced. In general the morphine can be withdrawn completely in from eight to fourteen days, and the scopolamine and dionine shortly afterward. The patients are not told immediately, but only after two weeks, that the morphine has been discontinued and that they are receiving inert injections. The dangers of this cure are minimal; occasionally only does one observe transient symptoms of intoxication. It is important that the scopolamine and dionine are freshly prepared; a solution more than three days old should not be used.

Albert Müller and P. Saxl have carried on some investigations concerning the tone of smooth muscles and the capacity of the stomach when the stomach is stretched to, say, ten times its normal capacity. The single muscle fibers of the walls do not stretch in proportion, but to only about double their normal length; the number of layers of muscle, however, decreases. This relation applies also to other hollow organs. The empty stomach is not lax, but a fairly compact hollow organ, which can be opened only by a definite amount of pressure. The normal filling with the ingested food occurs with a very slight pressure; this can occur only if the muscles stretch or the resistance to the thinning of the layers is reduced. If in an anesthetized animal a canula is fastened in the pylorus and it is sought to allow water to flow into the stomach, by inciting the act of swallowing by stimulation of the superior laryngeal nerve, the slightest increase of pressure suffices to stretch the stomach to the maximum extent and to thin the walls. In animals not under an anesthetic the stomach resists even a high pressure; if, however, we incite the act of swallowing, the organ may be filled with but slight pressure. There exists then in the vagus nerve a mechanism which governs the tone of the gastric muscles. Gastric atony may be explained as a discontinuing of the resistance of the stomach to a thinning of the layers of its musculature. It has been proved by the *x*-ray that, after the act of swallowing, food remains at the cardiac end of the normal stomach and slowly forces its way through the stomach. On the other hand, in an atonic stomach the food lies as in an empty sack. The gastric mechanism is influenced in various ways by medicines. These experiments were carried on on animals not under anesthetics, in which a gastric fistula had been made and a canula inserted. When the normal capacity of the stomach varied from 200 to 224 c.c., under the influence of physostigmin and strychnine it decreased to 80 to 90 c.c., but with atropine was 350 c.c. With narcotics the gastric capacity was greatly increased, up to 600 c.c. Adrenalin and cocaine were without effect; anesthetics produced pronounced dilatation. Alcohol at first caused an increase, then a decrease in the muscle tone. Cold fluids were without effect; very hot fluids caused a weakening, mineral waters a great increase of the tone of the stomach muscles.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 2, 1909.

Surgery of the Stomach.—The present situation in gastric surgery is summed up by John B. Deaver as follows: (1) The treatment of ulcer surgically is highly satisfactory, but not perfect in its results. (2) With less danger in operating because of our present improved technique, excision or resection of gastric ulcer will probably become more frequent. (3) Chronic dilatation of the stomach is curable by gastroenterostomy, whether the pylorus be patulous or not. (4) Gastroptosis does not respond to surgical treatment. (5) Neuroses of the stomach are fit for surgical treatment only when their cause, being without the stomach, can be removed. Operations on the stomach for functional gastric conditions are always failures. (6) Carcinoma of the stomach in many instances would be curable if diagnosis could be made early. Until our diagnosis is improved our results will continue to be poor. Unless we explore earlier and more often, and do not consider the responsibility of such procedure a grave one, we cannot hope to progress in the surgery of malignant growths of the stomach.

The Presence of Tubercle Bacilli in the Blood in Tuberculosis.—M. A. Dailey reports that blood from seventeen cases of tuberculosis (two of miliary and fifteen of advanced tuberculosis), inoculated into guinea pigs failed in every instance to produce the slightest evidence of the disease. Stained smears of the blood from the seventeen cases showed occasionally bodies resembling tubercle bacilli. He concludes that the only reliable test for demonstrating tubercle bacilli is animal inoculation and the production of the characteristic tuberculous lesions with the bacilli in them. This test applied to the blood of seventeen cases of miliary and advanced tuberculosis failed in every instance to demonstrate tubercle bacilli. It is reasonable to conclude, therefore, that virulent tubercle bacilli are not ordinarily demonstrable in the circulating blood of tuberculous patients. Staining tests (on which Rosenberger bases his arguments and conclusions) are not reliable. The results he obtains may be explained in at least three ways: (a) As attenuated tubercle bacilli; (b) as artefacts; or, (c) as acid-fast bacilli of some sort introduced as a contamination in some of the steps employed in staining, or deposited on the slide by the fingers in the process of cleaning or manipulation. This further conclusion seems warranted: That the demonstration of tubercle bacilli in the blood by means of staining methods is wholly unreliable and hence of no clinical value.

The Desirability of Further Extension of Undergraduate Nursing Service.—Frank W. Patch says that undergraduate extension service will settle the controversy between the advocates of two years and those of three years as a proper period for the nurse to spend in training; it will give the pupil a wonderful opportunity for further object study in her profession along social and humanitarian lines; it will relieve, in some measure, the financial drain in the conduct of the training school; it will produce a body of nurses with a more fully rounded edu-

cation, better grounded in the humanities, better fitted to handle the countless practical problems arising during sickness in the middle-class homes, and more suited to become centers of personal influence in later life; it will, in a large measure, meet a real and crying demand for an efficient nursing service on the part of a great self-respecting body of people who are able and willing to pay moderately for what they are evidently unable to have at "regular rates."

New York Medical Journal, September 4, 1909.

The Value of the Test Meal in Gastric Diagnosis.—Christopher Graham and Donald Guthrie regard the test meal as having a place in gastric diagnosis, but they caution against its too liberal interpretation independent of the clinical history. They analyzed carefully the gastric findings in 250 cases of ulcer of the stomach and duodenum and 150 cases of carcinoma, which had all come to operation and the correctness of the diagnosis established. They also included 100 cases of pyloric spasm due to appendicitis or gall-bladder disease. There was also 100 cases of gastric neurosis. For comparison the stomach findings of twenty-five cases of pernicious anemia are also added. They call attention to the fact that of three-fourths of the cases of ulcer that came to the operating table the patients do not show the high acids as commonly thought to be the case. The average age of these patients was forty-five years and the average duration of symptoms more than twelve years, both factors, age, and chronicity tending to reduce the acidity. Young subjects with developing ulcers have high acid tests. They regard decided food remnants in the test meal as a surgical indication. A large number of cases of gastric carcinoma must be diagnosed independently of the test meal findings; yet, on the other hand, there are a few cases in which the subjective symptoms are indefinite, and where the test meal throws the first light upon the real pathological condition present. They have been impressed with the frequency with which cancer develops upon an old ulcer. The tests in cases of pyloric spasm, taken independently of the clinical symptoms, vary little from those in ulcer and did not help them much in drawing definite conclusions. The cases of functional neurosis gave the greatest hydrochloric acid showing, but lacks the force of surgical argument, especially in food remnants, blood, and lactic acid. Apart from food remnants the cases of pernicious anemia show a test very analogous to cancer.

Tuberculosis and Congestion.—S. Adolphus Knopf says it is a sad comment on our present state of civilization that our prisons are the most congested centers of population now in existence, and as a result the mortality from tuberculosis among prisoners is three times as high as that of the general population. Efforts are now being made in many of the prisons to segregate the tuberculous prisoners and pay more attention to ventilation of cells and workshops. The next highest mortality is among the working classes who live in the crowded tenement districts. There must be a radical change in the housing and modes of living of the masses; otherwise they will never become masters of the situation, never be able to combat tuberculosis. Teach the people to keep the air fresh and pure in their living as well as in their working quarters, to keep their bedroom windows open at night, to report to a physician if they feel the well-known early symptoms of tuberculosis. Improve the living condition of the masses. Insist upon lower buildings and wider streets; replace the old tenement houses by model tenement houses, with roof gardens on each of them; multiply the parks and playgrounds; do away with this fearful congestion; utilize the suburbs of the large cities for individual homes of the masses; give the people an opportunity to live in a home somewhat closer to nature than the dark, dreary tenement houses of our overcongested cities.

True Versus False Opotherapy.—Charles E. de M. Sajous uses the word "true" to mean agents which can be used intelligently, that is, with a knowledge of the physiological effects produced, because their active principles are known. Thyroid extract belongs to this class as well as adrenal preparations. By "pseudo" agents he means those animal extracts that are used blindly. Thymus and mammary extracts can be cited as examples of these agents. He treats of four organic preparations (besides the thyroid, parathyroid, and adrenal products), which have stood out most prominently in the history of opotherapy, the testicular, ovarian, renal, and pituitary extracts. Granting that the only really demonstrated internal secretions are those of the thyroid, adrenals, and pancreas, and that their therapeutic products are the only legitimate ones, because their active principles are known, he proceeds to show that others can be raised to the same standard by a study of their properties. Spermin is the purest of testicular preparations. It not only raises the blood pressure, slows the heart, and produces all other physiological effects peculiar to the adrenal principles, but its solubilities are the same; it gives the same tests; it resists boiling. It has been found equally useful in disorders in which adrenal preparations had given good results. The inference that spermin consists mainly of the adrenal product suggests that it should not be regarded as specific to the testes, but instead a constituent of the blood at large; not only did this prove to be the case, but it was found in the blood of females as in that of males. Ovarian preparations are dependent upon the adrenal principle for their activity. Just as castration causes a decline of the temperature, so does removal of the ovaries; while both thermin and ovarin restore the temperature to normal. This corresponds with the influence on general oxidation he ascribes to the adrenal secretion. As is the case with the latter, ovarian preparations enhance metabolism, and the excretion of phosphoric acid. The resemblance of the physiological effects of ovarian extract to those of adrenal preparations is striking. No recorded experimental work justifies the conclusion that the kidneys have an internal secretion. There is, on the other hand, indirect testimony to the effect that, as in the organs just referred to, the adrenal principal is the main active agent. Pituitary extracts are active according to which of the two lobes of the gland is used to prepare them. Extracts of the anterior lobe are practically inert. Extracts of the posterior lobe causes a marked rise of blood pressure and slowing of the heart beat, these effects resembling in general those obtained from adrenal extracts, but differ in some details (Howell). Facts presented seem to justify the inclusion of testicular, ovarian, renal, and pituitary extracts in the adrenal group of organic extracts.

The So-Called Thymus Death.—An account of seven cases of sudden death in one family is recorded by J. P. Crozer Griffith. There were eight children, omitting the stillbirth and premature birth, all but the ninth breast-fed, and only one of them alive at the time of writing. The other seven died between the ages of one month and eight months, all well nourished, with uncertain diagnoses, and all with clinical histories nearly identical, namely, slight bronchitis, followed in one instance by extremely sudden death, in the remainder by the rapid development of cyanosis and dyspnea lasting some hours or a day, but without any symptoms suggesting stenosis; the condition in the ninth child being proved by autopsy not to depend upon pulmonary involvment. In the last case a very large thymus was found. It is a supposition only that with the clinical symptoms the same, and in view of the family relationship, the lesions also in the other children were the same as in the ninth one.

Primary Tuberculosis of the Mammary Gland.—William Fuller concludes that tuberculosis of the mammary gland is, perhaps, a more frequent affection than a study of the literature would lead us to believe. This affection occurs later in life than many reports would indicate, and its manifestations may not differ materially from a large number of other conditions both benign and malignant. The closeness with which mammary gland tuberculosis may imitate malignant disease, and the great difference in the operative procedure necessary for the cure of each condition calls for accurate differential diagnosis in all cases, not after, but before the application of any therapeutic measure.

A Simple Method for the Treatment of Suppurating Bubo.—J. A. Murtagh reports a method of treatment devised by Captain William L. Keller, Medical Corps, U. S. A. The points upon which the success of the treatment depend are briefly as follows: (1) Thorough application of the actual cautery to the infected ulcer. (2) Incision into healthy skin, usually in an area one to one and a half inches covering the bubo. (3) Thorough removal of the diseased glandular tissue and complete irrigation of the cavity. (4) Thorough drying of the cavity as nearly as possible by pressure, before introducing an emulsion of 10 per cent. iodoform, and rest in bed for a few days after operation. The advantages of this method of treatment may be summed up as follows: Immediate relief from pain and discomfort; rapid healing of the skin incision and of the diseased glandular cavity; absence of a painful and disfiguring scar; avoidance of a long, tedious period of recovery, usually experienced by other methods.

Journal of the American Medical Association, September 4, 1909.

Regeneration of the Cornea.—Meyer Wiener reviews the facts in regard to corneal regeneration and describes

the methods and results of a series of experiments on rabbits undertaken by himself in the anatomical laboratory of the Washington University, St. Louis. He operates by dissecting away a flap of cornea varying from one-half to two-thirds of its thickness and including one-half, two-thirds, or even the entire area of the cornea, the extent of surface bared seeming to have little or no influence on the general healing process or regeneration. Aside from the general aseptic precautions at the time of the operation, no special means were taken for the after-care, the rabbits being put in their cages without dressing or bandages. An antiseptic powder was dusted once daily over the cornea sometimes, when there appeared to be a virulent infection; when there happened to be an unusual amount of secretion, purulent or otherwise, which might tend to agglutinate the lids, they were washed with warm water and the secretion removed. The rabbits seemed to suffer no special inconvenience. There was no photophobia. The healing process is described in detail, and, in the rabbits which survived several months the regeneration was almost complete, being generally perfectly clear by oblique illumination as well as by transillumination, excepting an occasional small slightly hazy area. Microscopic sections were made which showed a gradual thickening of the cornea the longer the period from the operation.

Cyclodialysis in Glaucoma.—Arnold Knapp reports a number of cases of the operation of cyclodialysis for glaucoma which were specially selected to test its merits. This operation, suggested by Heine in 1905, consists in making an artificial communication between the anterior chamber and the suprachorioidal space, allowing a new channel for the escape of the aqueous humor and thus reducing the intraocular tension. The operation is performed under local anesthesia by making an incision in the sclera from 6 to 8 mm. posterior to the sclerocorneal juncture after reflecting a conjunctival flap and with bent spatula separating the ciliary body from the overlying sclera and breaking through the pectinate ligament. A quadrant of the iris periphery is then detached. Fifteen of these cases were of chronic glaucoma, one of congenital glaucoma, one of capillary adhesion to cornea, and one of glaucoma secondary to neuroretinitis with vascular changes and retinal hemorrhages. In the last three it was unsuccessful. In the first fifteen it was partially successful. In eleven of the chronic glaucoma cases the tension was reduced for observation periods varying from two years and nine months to two months. All the eighteen cases were such as not to promise much result from iridectomy. The operation is technically easy, much easier than a correct iridectomy. It did not aggravate the condition except for a macular hemorrhage in one and attacks of acute glaucoma in two. No vitreous disturbance or detachment of the chorioid was observed. It was repeated with benefit in three cases. Why it succeeded in some and failed in other similar cases cannot be explained. He says in conclusion: "It can be conservatively stated that cyclodialysis is of value in certain limited conditions; it is indicated in the advanced cases of chronic glaucoma, especially those in which iridectomy has not succeeded in reducing the tension. It cannot in any way replace the classical operation of iridectomy and its recent modifications in incipient cases of chronic glaucoma."

Anesthesia and its Dangers.—D. C. Moriarta says the danger of anesthesia is largely due to the anesthetist. He does not mean by this that some anesthetics are not in themselves more dangerous than others, but rather that the average patient can more safely take one of the dangerous anesthetics given by a skillful man than one of the safest given by an indifferent practitioner. The profession does not sufficiently realize its responsibility in this matter and he maintains that there is no justification for serious complications following anesthesia. We should raise the standard of the whole profession in this regard. The anesthetist should know the action and peculiarities of the drug he uses and give his whole attention to his own duties during the whole time he is employed. He should be in no hurry, should determine for himself the condition of the lungs and heart, and if not previously informed should ascertain the urinary condition. He should learn also whether there are loose teeth in the mouth and see if the patient is properly clothed. He should employ the method and the anesthetic with which he is thoroughly familiar and with which he can safely produce the lightest anesthesia under which the operation can be performed. Talking to the patient while getting him under the anesthetic is an advantage. He should never order the patient to take a deep breath, should have the necessary emergency remedies at hand, and remain with the patient until he is safely in bed and in good hands.

X-Rays in Dentistry.—G. E. Pfahler advises more extensive use of the *x*-rays by dentists. Every chronic obscure case should be tested this way, which is clean, aseptic, painless, and absolutely safe in the hands of an expert. The rays should be confined to the area examined and directed to the point of greatest interest. When the symptoms of disease are confined to a few teeth or roots the best results are obtained by the use of a small film directly in the mouth, but the use of the plate is necessary when the bone, accessory sinuses, or large dental areas are to be studied, and it is also convenient when searching for missing or unerupted teeth. The interpretation and study of the plate is more difficult than the making of it. The degrees of density as measured by the rays are as follows: The greatest density is shown by metallic fillings, then by root fillings; next in density is the enamel, then the dentine, and finally the cancellous tissue of the maxilla and alveolar process. A uniform white light is needed in reading the negative to bring out the details properly. He describes the pathologic conditions as they appear on the film or plate. Points of decay or abscess are indicated by a light area in the otherwise uniform density of the dentine. Incomplete filling of the root canal may be shown. A pericementitis is shown by a light space between the root surface and the mottled cancellous alveolus, and the root surface is rough instead of smooth. Abscesses about the tip of the root or in the alveolus also show light areas in which no cancellous structure can be seen. The use of the ray relieves the dentist from probing and the consequent risk of spreading infection. They also show exostoses and whorls or dense areas of bone, and pulp stones which may be the cause of neuralgias. One of the most important uses is to detect unerupted, impacted, and supernumerary teeth, and the absence of teeth where they should exist. Impacted teeth are rather common, especially the third molar, though other teeth may be affected. They often cause cases of severe neuralgia. Neglected affections of the maxilla and accessory sinuses are the cause of great suffering, and Pfahler points out the characteristics of the plate or film that indicate fracture, necrosis, tumors, and cystic degenerations. In the upper jaw the conditions are rather more difficult, but morbid conditions there can be nicely demonstrated. Lastly he mentions the therapeutic application of the rays, of which there have been enough reports to justify their use in obstinate cases and where other methods have failed. He has seen marvelous results in the treatment of sarcoma of the bones and sinuses. He has seen pyorrhea of the antrum, resistent to all other treatment, recover under the rays, and good results also in old and obstinate cases of pyorrhea alveolaris. Obstinate cases of idiopathic neuralgia will sometimes yield quickly.

Cataract Extraction by the Smith Method.—The Smith method of expression of cataract within the capsule, and the remarkable results, which have been reported and extensively discussed, are reviewed by D. W. Greene, who has utilized it in a number of cases and who describes the various steps of the operation. The remarkable results reported by Smith and practically confirmed by Arnold Knapp's observations of Smith's clinic at Jullundur, are explained by the marvelous skill of the operator and the comparatively early age at which cataracts develop in India. Greene has learned by experience that the percentage of success depends more on the attainment of a high degree of skill, technical knowledge, and the imitative faculty, than on any skill acquired in making the regular operation. He has had special instruction from Smith and further experience has confirmed his belief that the method is superior to any other method of extracting immature cataracts or to any method of artificial ripening. His own experience is, on the whole, favorable to the Smith operation. He sums up its advantages and disadvantages as follows: (1) Cataract can be removed at any stage; (2) no discission is ever necessary; (3) there is comparative freedom from postoperative inflammations; (4) there are no capsule entanglements, prompt healing is the rule; (5) the method is especially adapted to institutional work, one operation does all; (6) no ripening methods need be tried; (7) the result is better average vision, which does not change with time if the fundus conditions are favorable. The disadvantages of the method are the following: (1) The only important one is greater liability to loss of vitreous for the average operator; (2) from a cosmetic point of view the wide updrawn pupil (if it results) mars the appearance of the eye, while it may not be a disadvantage to vision; (3) and lastly, a skilled assistant is always necessary in performing the operation. He gives the statistics of his own operations by this method and says he does not wish to be considered a

champion of the Smith method until he has observed the ultimate results on white people in their own living conditions. He thinks, however, that it is a long step toward the ideal operation which we seek.

The Lancet, August 21, 1909.

The Early Signs of Rheumatism of the Heart.—A. M. Gossage gives detailed consideration to the recent observations of Dr. Carey F. Coombs in regard to rheumatic myocarditis, and in conclusion emphasizes the statement that while pericarditis gives the usual well-recognized signs of its presence, recent endocarditis causes no physical signs whatever. Affections of the myocardium in rheumatism may be divided into the inflammatory and the toxic. Inflammatory lesions cause a loss of tone in the muscles which surrounds the mitral valve allowing of mitral regurgitation. Thus an apical systolic murmur is the sign of rheumatic myocarditis, and is, indeed, the only sign of inflammation of the heart apart from pericarditis. In the majority of cases the presence of such a systolic bruit is diagnostic of myocarditis, but in a small minority a regurgitant murmur may result from general dilatation without any inflammation Poisoning of the heart muscle in rheumatism causes a general dilatation of the heart and sometimes a mitral diastolic murmur. Dilatation may or may not be associated with inflammation of the myocardium, but the diastolic murmur may be taken to imply an absence of myocarditis at the time it is heard. As far as the immediate welfare of the patient is concerned the toxic action of the rheumatism is more important than the inflammatory, since it is to the consequent failure of tonicity and contractility that death during an attack is due. For the future welfare of the patient the inflammatory lesions become of chief account. Myocarditis is probably always associated with endocarditis, so that there is danger of permanent damage to a valve and the inflammation in the muscle itself may lead to such damage that tone is never regained, leaving a permanent widening of the orifice. Such occasional permanent damage to the muscle by the toxin would explain the different behavior of different hearts after rheumatism. It would seem that there is a tendency to exaggerate the importance of myocarditis in rheumatism. The more pressing danger comes from the action of the toxins on the cardiac muscle.

Antityphoid Vaccination with Attenuated Live Cultures.—Aldo Castellani describes the method of preparation of the live typhoid vaccine and his experiments upon both men and animals which lead him to the following conclusions: (1) The use in man of the live typhoid vaccine prepared according to the method described (heating the non-virulent broth cultures at 50 C.) is not dangerous. It probably induces a higher degree of immunization than the ordinary vaccines consisting of dead cultures. (2) Though both inoculations may consist of live vaccine without danger, the routine method of antityphoid vaccination which he recommends and uses is the inoculation of one-half cubic centimeter usual dead vaccine (Wright) followed in a week's time by the inoculation of one cubic centimeter of live vaccine. (3) Mixed vaccines may be prepared by using dead or live attenuated cultures of typhoid and dysentery, or typhoid, paratyphoid, and dysentery. The inoculation of mixed vaccines may be of advantage in some cases, but the subject requires further investigation as regards its efficacy in man.

An Unusual Type of Stomatitis in an Infant.—A. H. Brehaut recalls the fact that the severer types of stomatitis occur especially between the age of two and 12 years, while the case which he reports was that of an infant four months of age, in whom the acute onset and great local reaction showed the infection to have been local and not constitutional in origin. On examination, the left cheek was found to be very much swollen and shiny, the swelling not localized. The cheek was extremely hard, tense, and tender. The inside was dusky, and, about half way back on a level with the alveolar border of the lower jaw, there was a small patch about the size of a No. 4 shot which had the appearance of threatening gangrene. The temperature was 104° and the pulse uncountable. Surgical interference was refused. A lotion was prescribed for application to the interior of the cheek and potassium bromide was given internally. On the following day the cheek was somewhat improved and continued to improve so that a week from the onset of the attack it was normal and the child subsequently remained in good health. Recovery occurring without any loss of tissue negatives the view that it was a case of gangrenous stomatitis. There was no evidence of its being ulcerative stomatitis. When first seen it seemed very unlikely that such a young child would make such a recovery from so acute an infection in such a short time

A Case of Transient Ataxia Following Diphtheria.—H. O. Butler reports the case of a man, 26 years of age, who had taken in all 26,000 units of antitoxin. From the fourth to the eighteenth days of his illness, vomiting occurred shortly after taking food and marked constipation was present. A large variety of pills and enemata had next to no effect and it was thought that there was paralysis of a portion of the lower bowel. Five weeks after the onset of his illness he complained of difficulty in swallowing which passed off in about a fortnight when he began to complain of numbness and tingling sensations and his gait became typically ataxic. Knee jerk was present. His condition grew worse until he became absolutely and completely helpless. This state lasted for a month and then gradually cleared up with the exception of the right arm, where there was stiffness which lasted about five months. At no time were there eye changes or wasting of any muscles. Treatment consisted solely in giving a mixture containing strychnine. The pathology of the case is simple; peripheral neuritis of the afferent nerves accounts for all the symptoms.

British Medical Journal, August 28, 1909.

Peripheral Circulation and Its Treatment.—Sir James Barr tells of the importance of the arterioles and capillaries and the pressure within. All agents, such as dry heat, warm baths, massage, and passive exercises, which relax the arterioles, increase the freedom of flow into the capillaries and raise the lateral pressure in them and lower the arterial pressure. If the arteries are at all rigid, as in the aged, the injudicious use of baths and vasomotor relaxants very readily gives rise to weariness, languor, faintness, and sickness. If there is a great difference between the systolic pressure in the aorta and the resistance, such as occurs in free aortic regurgitation or very advanced arteriosclerosis, the arterial wave may be carried to the capillaries and give rise to pulsation in these vessels. This implies great waste of cardiac energy, and under such circumstances vasomotor relaxants must work mischief. Vasomotor tonics and such agents as diminish the lime salts and improve the muscular tone constitute the best treatment. Any obstruction to the outflow from the capillaries diminishes the velocity in them. Hence the congestive treatment of joints and other local lesions. In alcoholics the arterial pressure falls, the diastolic pressure in the heart rises, the right ventricle gets dilated and tricuspid valve incompetent, and the blood is thus dammed back in the liver. From the fall in the arterial pressure the pressure in the portal vein also diminishes, and consequently there is a fall both in the velocity and filtration pressure in the portal capillaries; this gives rise to a concentrated transudate both in albumen and leucocytes which soon leads to a multilobular cirrhosis. This obstructs the portal circulation, which raises the pressure in the intestinal capillaries and gives rise to increased filtration from them. The indications for treatment in these cases are: Stop the alcohol, lessen the input of fluid, and raise the arterial pressure. An intestinal antiseptic and a colon bacillus vaccine are often useful. A dose of Epsom or Glauber salts in a small quantity of water is better than any imported saline. Nicotine causes a vasomotor paralysis in young males. There is occasionally a deficiency of lime salts and slight albuminuria. Such patients should take plenty of exercise and wear a tight abdominal belt. They should be given glycerophosphate or lactate of lime, and when a purgative is required, sulphate of magnesium. They should be on a liberal dry diet. Tobacco and alcohol should be forbidden. Keep the bowels open and as aseptic as possible. Buttermilk is a good antiseptic for the intestinal tract. In patients with granular kidneys the lime salts are usually excessive, and hence milk is not a suitable diet. The nitrogenous elements must be cut down and salt almost eliminated from the diet. The patient can have plenty of hydrocarbon, carbohydrates, fruits, and vegetables, except such as contain oxalic acid. He should have the benzoates, the citrates, and any decalcifying agents. In large congested, chocolate-colored kidneys, when the capsule is stretched to its utmost capacity, the only salvation for such kidneys is to freely incise the capsules and kidneys. In acute tubular nephritis the lime salts are not, as a rule, excessive; hence milk is admissible. Medicinally the following drugs are useful: Antimony, the benzoates, the citrates, the acid tartrate of potassium, saline purgatives, hot-air baths.

The Crescendo Murmur of Mitral Stenosis.—F. M. Brockbank reviews the main theories concerning the rhythm of the crescendo murmur of mitral stenosis, for convenience he speaks of mitral stenosis only as being

the *a-s* lesion most commonly met with. The two chief theories of the rhythm of the crescendo, or presystolic murmur, are: (1) That this murmur is a direct current murmur, and occurs while blood is passing from the auricle into the ventricle, and is caused in part or wholly by systole of the auricle. (2) That it is a regurgitant murmur, and due entirely to systole of the ventricle. In conclusion he submits that he has shown that the *a-s* rhythm of the crescendo murmur is not only highly disputable, but even entirely fallacious, and that the murmur is early *s-s* in rhythm.

Observations Concerning the Blood in Chorea and Rheumatism.—Experiments and observations made by Charles J. Macalister tend to confirm the suspicion that there is less real association between chorea and rheumatism than is generally thought to be the case, and that chorea may be due to an infective toxemia of distinctive character.

The Preventive Treatment of Puerperal Eclampsia.—Alex. Milne Bankier believes that the toxemia of this disease to be of an acid character. He examines the urine in all cases of pregnancy at the seventh month. If albumen is found, he orders the patient to bed and keeps her there until confinement. The diet is principally milk; all other nitrogenous food is forbidden. The preventive treatment is the use of potassium acetate (a neutral salt which becomes alkaline when taken) in sufficient doses to keep the urine alkaline. The urine is examined every three days until labor sets in. From his experience of twelve consecutive cases, no convulsions will occur during labor or after delivery. This agent will not cure the patient of her albuminuria, but it does prevent eclampsia.

Münchener medizinische Wochenschrift, August 10, 1909.

Anemia of Infancy.—J. Katzenstein discusses the cases of anemia in infancy which occur unassociated with any acute illness. This occurs especially in children of the better classes who have been nursed or fed for a long time on milk alone. Milk, according to Bunge, contains less iron than almost any other food. The iron of milk ash is only one-sixth that of the ash of an infant. This form of anemia rarely occurs in children of the lower classes who early obtain varied food such as the parents eat. On the strength of this Katzenstein has been giving a diet rich in iron early in infancy. His routine feeding consists in adding at three months of age once a day, meat broth containing at first one-half of the yolk of an egg, later an entire yolk. At four to five months he gives a porridge made of zweibach, butter, milk, salt, sugar, and the yolk of an egg. From six to nine months he gives spinach. At ten months meat, sausage, veal, and poultry. At the end of the first year the milk is reduced to one-half to three-quarter liters and a mixed diet given. Since giving this diet he has had no cases of anemia except where associated with syphilis or some other illness. In cases of anemia which have come to him prompt recovery has followed the use of this diet. The hemoglobin of an infant of four to six months on a milk diet is usually from 80 to 90 per cent. On the iron containing diet the hemoglobin remained at 100 per cent. during the entire first year. Dried egg yolk contains ten times, and dried spinach fifteen times, the iron of dried milk. Katzenstein has also noted that he has had no cases of rickets develop in his infants on this diet, and that rickety children very rapidly recover on it.

Carbonic Acid Snow in Skin Diseases.—Zweig states that the action of solid carbon dioxide is due entirely to the intense cold (—90° C.). The action of the snow can be regulated by the length of time it is kept in contact and the pressure exerted. The carbonic acid cylinder is put flat on the floor and the snow caught by placing a small chamois bag resembling a tobacco pouch over the outlet. The gas is allowed to escape intermittently from three to five seconds at a spurt. The snow so formed is packed into glass tubes, 10 to 15 cm. long, and of a diameter dependent upon the size of the lesions to be treated. He reports twenty-five cases treated by this method with excellent results. The list includes nevus, angioma cavernosum lupus erythematosa, lupus vulgaris, and epithelioma.

Deutsche medizinische Wochenschrift, August 5, 1909.

The Opsonic Index in Typhoid Carriers.—Gaehtgens has studied the opsonic power of the blood serum of a series of typhoid convalescents and of sixteen chronic typhoid carriers, and concludes from his investigations that in persons who have had typhoid fever, but are not carriers of the typhoid bacillus, there is usually an increase in the opsonic index for a period of three to four months after recovery from the disease, but that after that the index again returns to normal; while in chronic typhoid carriers there is as a rule a considerable increase in the opsonic index over a long period of time. The indices in the carriers varied from 1.4 to 3.9. In thirteen of the sixteen cases it was 2.0 or above, and in five of them over 3.0. Two cases that were definite carriers gave positive Widal reactions and high opsonic indices, though no previous history of typhoid fever could be obtained. The rest gave histories of the disease, the date varying from one-half to twenty-nine years before. He further states that agglutinins and opsonins were often present together in the carriers, but that the presence of one of these antibodies did not enable one to say definitely that the other was also present.

A Rare Symptom of Atrophic Cirrhosis of the Liver.—Moehring reports a case in which there was marked ascites, muddy icteroid complexion, and other symptoms of cirrhotic liver. The point of interest in the case was the sudden onset of copious hemorrhage from the navel. The blood was venous in character. Examination showed in the navel a vein the size of a lead pencil with a rupture about as large around as a match. The hemorrhage was controlled by ligation. It was thought probable that the cause of the bleeding was the presence of a patent umbilical vein, engorged by the cirrhosis and possibly ruptured by scratching. At autopsy, however, it was found that there was no such vein, but that there was a small navel hernia in which was incarcerated a tab of omentum, and that the hemorrhage came from a greatly engorged and swollen omental vein.

A Contribution to Hirschprung's Disease.—Sommer reports the case of a boy of thirteen years of age, previously healthy, who was taken ill suddenly with the symptoms of intestinal obstruction which was relieved by a cecal fistula. Later median laparatory showed an enormously dilated sigmoid. This was brought out through a third incision over the left Poupart's ligament and sewed to the skin. After two days the loop was resected. The wounds healed and the boy made a good recovery. The point of especial interest is the sudden onset of abdominal symptoms in a case of giant colon in a boy who had been to all appearances perfectly healthy.

The Summer Death Rate for Infants.—Finkelstein discusses the cause of the high mortality among infants in the summer time, and says that in a small degree it is caused by cases of heat stroke with acute choleraic symptoms. In the greater part it is due to the increase in fatal subacute digestive disturbances, which begin during the hot days, and, as a rule, does not reach its climax until the hot period is ended. The rôle of contaminated milk as the sole cause of the disease in artificially nourished infants is not proved. The direct effect of the heat on the child must be considered at least. It is quite possible that the heat so effects the bottle baby that it loses its tolerance for a food in itself innocuous, so that the bottle baby more easily contracts disease than the breast baby. It must also be noted that the commonly weak and ill bottle-fed infant is much more prone to suffer from hyperpyrexia than is the breast-fed baby at the same temperature.

Physical Therapy of Pulmonary Edema.—Kulenkamp reports the case of a man of sixty-three with chronic cardiac lesions and dyspnea in whom pulmonary edema occurred. Noticing the difficulty of expiration, the author thought to help the patient in his expiratory efforts by forced compression of the thorax. This was done synchronously with the patient's own expirations. The procedure gave the patient a very great degree of comfort and the edema of the lungs also rapidly cleared up, the patient meanwhile expectorating large amounts of fluid.

The Value of an Examination of the Eye Grounds in the Diagnosis of Anemias.—Hesse has made routine examinations of the eye grounds in all cases of anemia. In fifty cases of definite pernicious anemia examined retinal hemorrhages were found in forty-seven. In fifty-one cases of severe secondary anemia and sixty-four cases of malignant tumors, no retinal hemorrhages were discovered. He concludes: (1) Retinal hemorrhages belong to the picture of pernicious anemia. (2) All other anemias, especially the cachetic, the carcinoma anemias, show no retinal hemorrhages. The occurrence of retinal hemorrhages in a severe anemia suggests pernicious anemia, while their absence would point toward carcinoma.

Book Reviews.

The Greatest Good of Mankind—Physical or Spiritual Life. By William Wenzlick, LL.B., M.D. Chicago: Published by the Author, 1909.

The aim of this book, as told in the introduction, is to arouse and encourage people of ability and power to unite in an effort for the amelioration of suffering humanity. The book is in the form of a dialogue between Dr. Fact and the Reverend Faith. Dr. Fact deplores existing conditions, and charges the Church with failure to practise the teachings of Jesus, in that "it has not prevented, but has actually produced avoidable evils." The validity of Dr. Fact's claim, however, is not proven. Dr. Faith credits Christianity with "the greatest progress in the moral and spiritual nature of man." In so far as the author sought to start the reader thinking on this all-important theme he has succeeded; but as to the question he propounds in the title of his book, it is left unanswered.

Studies from the Rockefeller Institute for Medical Research. Volume IX., 1909.

This volume comprises forty-three articles reporting pieces of research work carried on at the Rockefeller Institute in New York and in other scientific laboratories, by men who have been enabled to carry on their work by grants from the institute. The papers have appeared previously in the journals, but their collection in one volume serves to bring to the attention the work which is being done in America through the generosity of Mr. Rockefeller. The articles which strike the attention with especial force are those by Flexner and Jobling on the anti-meningococcus serum, by Carrel on transplantation of blood-vessels, and by Hideyo Noguchi on his simpler bedside modification of the Wassermann test. It is difficult, however, to select from such a mass of valuable material when each of the forty-three articles throws some light on some subject of interest in bacteriology, physiology, chemistry, or the kindred sciences. It is unfortunate that the volume is published as it is as a collection of reprints from various journals, a fact which leaves the pages numbered as they were in the original and makes it a difficult matter to find any especial article.

Conservative Gynecology and Electrotherapeutics. A Practical Treatise on the Diseases of Women and Their Treatment by Electricity. By G. Betton Massey, M.D., Attending Surgeon to the American Oncologic Hospital, Philadelphia; Fellow and ex-President of the American Electro-Therapeutic Association; Member of the American Medical Association, etc. Sixth Edition, Thoroughly Revised. Illustrated with twelve original full-page chromo-lithographic plates and fifteen full-page half-tone plates of photographs taken from nature, and numerous engravings in the text. Philadelphia: F. A. Davis Company, 1909.

Since Apostoli introduced the use of electricity into the treatment of diseases of women, studying the chemical changes which take place at the positive or the negative pole of the galvanic current and applying these principles to the local treatment of inflammation and neoplasms of the female genitalia, the idea of electrogynecology, though probably scoffed at by the greater part of the medical profession, has nevertheless received a certain number of enthusiastic advocates who claim most excellent therapeutic results from the local application of electricity in gynecology. The author of this book is possibly the most enthusiastic and one of the best known electrotherapeutists in America. The fact that the book has run through five editions in the last twenty years speaks for its general acceptance by those interested in this form of treatment. The book is in two parts. The first opens with directions for gynecological examination, and goes on with the principles involved in the use of electricity in treatment, with directions for the application and descriptions of the instruments used for the treatment of the general system, vagina, uterus, skin, and tumors. Metritis, salpingitis, and ovaritis are discussed at some length, as is the subject of fibroid tumors. Cancer of the mammæ, uterus, and rectum and their treatment by cataphoric needling come in for separate chapters. Visceral displacements, relaxed abdominal walls, sterility, impotence, and ectopic gestation are all brought up and discussed in relation to the treatment by electricity, and finally the diseases of the urethra and bladder and the removal of hair and nevi are considered. Many cases are reported and directions for treatment are given. The second part of the book gives the physics of medical electricity, describes the common kinds of electrical apparatus, and devotes a chapter each to the x-rays and high frequency currents. The book is well bound and printed on good paper. The illustrations are numerous and clear; some, in fact, especially the photographs of the professional artists' model, are of a clarity in very bad taste in a scientific work. The book is, all in all, a clear exposition of the author's enthusiasm for electrogynecology, but fails at times to pay the attention to details of method, strengths of current to be used, and other minor points of absolute necessity in describing a method of treatment of which the vast majority of the medical profession are in a state of dense ignorance.

Clinical Lectures on Neurasthenia. By Thomas Dixon Savill, M.D., Lond.; Physician to the West End Hospital for Diseases of the Nervous System, Welbeck Street, London; formerly Medical Superintendent of the Paddington Infirmary; Examiner in Medicine in the University of Glasgow; Assistant Physician and Pathologist to the West London Hospital. Fourth Edition. New York: William Wood & Co., 1909.

The "great American disease" has been a fruitful topic for discussion and publication, and most authorities give us an unfavorable outlook both for recovery in individual cases and for the abolition of its development and spread as a universal disease. Our English contemporary, however, Dr. Savill, has maintained for some years that the determining causal factor underlying neurasthenia, in the majority of cases, is an autointoxication, the basis for which is discoverable and frequently removable, and he thus materially fortifies a better prognosis. The appearance of a fourth edition of Dr. Savill's "Lectures on Neurasthenia" attests the popularity of his views. He states in his preface that he is now testing the efficacy of vaccines made from the prevailing intestinal microbes found in the stools of patients with neurasthenia due to autotoxemia of gastrointestinal origin. The writer does not deny that mental symptoms may predominate in some cases of neurasthenia, but thinks that the clinical picture points, nevertheless, as a rule, to a derangement of the entire nervous system. Readers will find in the book a fuller discussion of the physical than of the mental characteristics of the disease.

Hand-Book of Diseases of the Rectum. By Louis J. Hirschman, M.D., Detroit, Mich., U. S. A.; Fellow American Protologic Society; Lecturer on Rectal Surgery and Clinical Professor of Proctology Detroit College of Medicine; Attending Proctologist Harper Hospital; Consulting Gynecologist Detroit German Polyclinic; Collaborator on Proctology "Physician and Surgeon"; Editor "Harper Hospital Bulletin"; Chairman Section on Surgery Michigan State Medical Society; ex-President Alumni Association Detroit College of Medicine, etc., etc. With 147 illustrations, mostly original, including two colored plates. St. Louis: C. V. Mosby Medical Book & Publishing Co., 1909.

Dr. Hirschman believes that many of the patients afflicted with sigmoidal, rectal, or anal diseases, who are referred to the specialist for treatment, or to the general surgeon for operation under general anesthesia, could be treated satisfactorily in the office of the practitioner. With this idea in view, the author has confined himself to the consideration of those conditions which are amenable to office treatment. The first three chapters deal with the anatomy, symptoms of rectal diseases in general, and the examination of the patient. Then follow chapters on constipation and obstipation, fecal impaction, pruritus ani, anal fissure and ulcer, abscess of the anorectal region, fistula in ano, hemorrhoids, rectal polypi, hypertrophied anal papillæ and cryptitis, proctitis and sigmoiditis, and prolapse of the rectum in children. A chapter on "Dysentery" by Dr. John L. Jelks of Memphis, Tenn., and one on the "Feces and Their Examination" by Dr. George W. Wagner of Detroit have been included in the book. The technique of the use of local anesthesia in the treatment of anorectal disease has been thoroughly described. Space has also been given to the consideration of the limitations of office treatment and the indications for other measures. In the treatment of chronic constipation the author claims that the best results are obtained by "direct stimulation of the atonic rectum and sigmoid." In speaking of the relief of pain in children after the cauterization of the rectum for mild degrees of prolapse, Dr. Hirschman advises the use of codeine in $\frac{1}{8}$ to $\frac{1}{4}$ grain doses, in a child $1\frac{1}{2}$ to 3 years old. This seems to the reviewer as a pretty large dose for a child of that age. Dr. Holt in his book on "Diseases of Infancy and Childhood" puts the dose of codeine for a child of one at 1/60 grain, and of five years 1 to 1/8 grain. Except for a couple of typographical errors the book is well written. It should be of use to those who wish to become proficient in the diagnosis and treatment of anorectal diseases.

Society Reports.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-eighth Annual Meeting, Held at Fortress Monroe, Va., June 4 and 5, 1909.

THE PRESIDENT, DR. CHARLES E. QUIMBY OF NEW YORK, IN THE CHAIR.

First Day, Friday, June 4.

President's Address.—Dr. CHARLES E. QUIMBY of New York delivered this address, and chose as his subject "The Element of Rationality in Medical Science." He said it was impossible not to recognize, and folly to deny, that medicine, using the term in its broadest meaning, was to-day in such condition as to cause the deepest humiliation and to justify the gravest anxiety for the future. This condition was manifest subjectively in every branch of work, and objectively in a rapidly increasing loss of public confidence which could not be checked by hiding one's head in the sands of conceit. It might be possible to attribute the tumultuous eagerness with which the ignorant and moderately educated turned for help to the newest "pathy" that bedecked and disguised some fragment of truth with the gaudy robes of sophistry and magniloquent falsification to an inherent tendency of human nature to follow after new gods, rather than to waning faith in scientific medicine, were the stake at issue something less than health and life. President Hadley of Yale, speaking for the scientific public, had cried "Give us physicians, not pathologists" and it implied a high degree of mental amaurosis not to "see ourselves as others see us." Thoughtful men no longer presumed to deny that medical education was producing men who were expert technologists, but devoid of the most fundamental principles of practical medicine, while the synthetic chemist was transforming the mass of the profession into empirical automata. Abundant proof of the justice of President Hadley's statement was always at hand. The irrationality of the conduct of medical men was all the greater when the remedy was so simple. That was a frank and honest confession of the impossibility of teaching men everything in even four years, and an equally honest recognition of the relative value of castor oil and graphic chemical formulæ in the conflict with disease. Proven truth and theory, probability and possibility, pure chance and blind empiricism, each and all had their legitimate place in medicine, and upon each, at one time or another, one was compelled to base momentous action. And by reason of this compulsion came the basic lapse from rationality that permeated and weakened the entire body of medical science. It was the failure to hold each of the enumerated terms strictly to its proper place and value which, under the seductive influence of the ambition to have all work truly scientific, ended in the assumption that everything could and must be explained. As a result medical men accepted the most plausible, or the first suggested explanation of condition or process, simply because it was possible, adopted and proclaimed it as truth, and speedily forgot that they were joining that great majority who "knew so many things that aren't so." Intelligent and conscientious men presented some of the most serious obstructions to scientific development ,and they were of two types and opposite extremes of thought. The one was represented by the German mind, of which the individual elements had become so profoundly erudite, and so edematous with the consciousness of that erudition that all "made in Germany" intellectual products were assumed *a priori* to be absolute truth. The other type was the man who met every fresh presentation of a discovery with the *ex cathedra* proclamation *non credo.* Every branch of science had long since recognized the law that newly discovered truth must pass through three stages before it became potential. In the first, those to whom it should appeal say: "It isn't true"; in the second they say "it doesn't amount to anything, anyway"; and in the third they all declare "That's just what we have always said." With regard to the realm of therapeutics, was it possible not to blush and smile when one read the list of new drugs approved by the "authorities" of the American Medical Association, which grew like the green bay tree? And approved solely on the basis of their chemical composition. Yet those untested weapons were what were being given to the inexperience of youth. Despite their ever-increasing number, there went with them no word of warning or direction as to how they acted; nothing save the name of the target at which they might be hurled. Physiological action was preserved only in the museum of pathological curiosities. Was it any wonder, then, under such circumstances young men lost faith in medicine? The attainment of harmony, and, therefore, the development of a permanent, unassailable system of scientific medicine, was possible in but one way. The first and fundamental requisite was submissive recognition of the true nature of disease, as the physiological manifestation of the organism's struggle for existence under special conditions. The second essential was an equally definite recognition of those manifestations as of two distinct forms, dynamic process and mechanical or chemical result. And the third, a clear appreciation of the fact that intelligent and harmonious adaptation of the forces brought to the support of the systemic activities, was possible under the guidance of logical theory. Dr. Quimby said he was not ignorant of or blind to the value of what had been done, but progress was measured by the net results of gain and loss, and nothing could be counted as gain which was not permanent.

A Movable Camp for Invalids, Neurasthenics and Others.—Dr. J. MADISON TAYLOR of Philadelphia read this paper. A novel and attractive suggestion had been made to him by Mr. Frank Pinkly of Casa Grande, Ariz., which embodied so many meritorious points that he asked the privilege of presenting it to the Climatological Association. He had formulated plans which were appended. Whether they could be made available or not needed a full discussion, not only here, but by men of practical experience. In brief, the proposition was for a good manager and physician to organize a force of skilled packers, teamsters, cooks, and helpers; secure the necessary outfit—tents, wagons, teams, saddle-horses, etc.; establish bases of supplies, map out routes, and run a movable camp. The design was to offer to invalids all the essential comforts and advantages of a sanatorium, yet add change of scene and circumstance. The camp could remain in one place just so long as season, circumstance, or taste might determine; then be shifted elsewhere. The course, or trail, might, for instance, start in the low countries (*e.g.*, at 1,400 feet in the Salt Valley) in the spring and gradually ascend into the high lands (6,000 to 7,000 feet) as the hot weather advanced, and finally descend toward the low lands again as winter approached. "Roughing it" was no part of the scheme. Persons weakened by disease, or over-susceptible to fatigue, should never be permitted to exhaust themselves by effort or anxiety, but should be provided with all reasonable comforts. Cows and hens could readily be moved from one site to another, furnishing plenty of fresh milk and eggs. The only limit to luxuries, in-

deed, would be the cost. Nor need this be prohibitive under judicious management and intelligent cooperation. To stationary sanatoria there were many cogent objections, among which were tedium, isolation, restricted amusements, and the like effects of long periods of enforced waiting for the tide to turn and set strongly favorable. On the other hand, a movable camp provided many salutary stimulations. Once in so often, every week or two, a change of scene and local conditions was provided. The patient might be conveyed in a comfortable vehicle, or, if strong enough, might ride a horse. He might fish and hunt a little; photograph, sketch, or watch others so disport themselves. Nothing was more delightful than the common incidents of open air camping; the open fire, the agreeable efforts to make oneself comfortable in the new surroundings, always with abundant help and attention, wholly freed from anxieties. About the time that monotony began to pall the camp was transferred to a new site, fifteen or twenty miles up the trail, to new surroundings, varied scenes and backgrounds. All this provided material for conversation, and, above all, for letters to family and friends. Whatever objections might arise, they may readily be met. For instance, one or two of the party might be too weak to travel; then a camp could be amplified and they could remain till able to hit the trail again. Those who had had much experience with protracted invalidism knew well that even pretty wretched persons often, indeed usually, exhibited astonishing capacity to move on, fortitude and resourcefulness during transportation. They often improved steadily and unexpectedly. The outline of the plan Mr. Pinkly had developed was presented in his own words.

The Incidence and Causes of Tuberculous Hemoptysis.—Dr. James M. Anders of Philadelphia read this paper. He said that the pathological etiology of hemoptysis fell naturally under two heads: (a) Hemoptysis caused by congestion of the bronchial mucosa and lung texture, and (b) that due to ulceration or erosion of blood-vessels or rupture of miliary aneurysms. The usual source of early hemorrhages in the course of pulmonary tuberculosis was the pulmonary vessels rather than congestion or erosion of the bronchial mucous membrane. Profuse or fatal hemorrhages tended to develop in cases in which the processes of softening and liquefaction progressed acutely and did not present endarteritis. In the majority of cases, however, pathological changes in the walls of the pulmonary vessels with aneurysmal dilatations preceded hemorrhages of advanced tuberculosis. His collective investigations embraced a totality of 5,891 cases of tuberculosis. Hemoptysis was manifested earlier in life in the female sex than in the male; the increased incidence in favor of the former sex, however, was confined principally to the first two decades of life. After the 30th year the numerical results showed a preponderance of cases in favor of the male sex. Profuse and fatal hemorrhages were less common in the female than in the male. As to seasonal influence, it might be said that hemoptysis in the course of tuberculosis was most prevalent during the months of December, January, and February. The latter statement was directly opposed to the preconceived notions of most writers, who contended that the spring and summer months gave the highest incidence. Multiple hemorrhages occurred in the majority of cases in which hemoptysis was among the clinical features. Of a totality of 3,142 cases of tuberculosis, recurring outbursts took place in 1,028, or 51.5 per cent. The great importance of hemoptysis as a diagnostic feature of tuberculosis rendered further observations along the line pursued in this paper extremely desirable.

The Prognosis of Febrile Cases of Pulmonary Tuberculosis.—Dr. Harry Lee Barnes of Wallum Lake, R. I., read this paper, and offered the following conclusions: (1) Patients who left the sanitarium against the physician's advice from lack of intelligence or unwillingness to sacrifice pleasure and comfort, lost over one-half of their chances of recovery. (2) The subsequent histories of patients at the Rhode Island State Sanitarium showed that the results of treatment of pay patients were less favorable than those of all patients. (3) Of 153 febrile cases an extension of the lung disease was indicated by an increase of physical signs in 50 cases, or 32.6 per cent., and by the appearance of signs in lobes previously clear in 33, or 21.5 per cent. (4) The average number of fever patients under observation from one to four months was 106, and of this number 11, or 10 per cent., developed cavity signs. (5) Of 18 patients under observation while cavity signs developed, 17, or 94.4 per cent., had fever. Thirteen, or 76.4 per cent., developed cavity signs within six weeks from the onset of the fever. (6) Of 16 patients in whom development of cavity signs was observed, 13 died in periods varying from 2 to 14 months, the average duration of life being 8.9 months. (7) Of 24 fever cases having cavity signs on admission, 21, or 87.5 per cent., died within two and a half years, the average duration of life being 13.9 months. (8) Only 8.5 per cent of febrile cases whose pulse averaged over 100 were well 27 months after discharge. (9) It was of comparatively little importance whether the average daily maximum temperature was 100°, 101°, or 102°, the duration rather than the height of the fever was the deciding factor in the prognosis. (10) The subsequent histories of febrile patients taken 27 months after the onset of fever showed, that of 62 cases who had fever 1 to 4 weeks, 59.6 per cent. were dead; of 39 cases who had fever 1 to 2 months, 69.2 per cent. were dead; of 11 cases who had fever 2 to 3 months, 72.7 per cent. were dead; of 12 cases who had fever 3 to 4 months, 75 per cent. were dead; of 13 cases who had fever over 4 months, 77.7 per cent. were dead. (11) Of 93 cases in which the fever was reduced after periods of treatment averaging 5.9 weeks, there were 24, or 25.7 per cent., well; 18, or 19.4 per cent., living, and 51, or 54.8 per cent., dead. (12) Of 44 cases in which the temperature could not be reduced after treatment from one to six months, 40, or 90.9 per cent., were dead, the duration of life varying from 1 to 18 months, and the average duration of life after the onset of the fever being 6.7 months.

The Lautier Reaction and Some Studies in Controls.—Dr. David R. Lyman of Wallingford, Conn., read this paper. He said that in the *Province Médicale*, February 8, 1908, Lautier reported cutaneous tuberculin reactions for which he claimed a greater degree of accuracy than was obtainable in any other skin test, and which had the recommendation of being the simplest of all. With regard to the method of application, Lautier, without any preparation of the skin, applied to the outer surface of the arm two or three drops of a 1 per cent. solution of old tuberculin on a pledget of absorbent cotton. This was covered with a guttapercha shield and held in place by a dressing for 48 hours. The reaction consisted of the appearance of vesicles containing a colorless liquid and set on raised reddened papules, usually discrete, sometimes agminated. These usually dried and disappeared in from 3 to 10 days. Dr. Lyman said that he had used this test simultaneously with those of v. Pirquet and Ligniere in 58 patients in the Gaylord Farm. Excluding two cases which did not

react to the subcutaneous method, 56 cases were reported in which the diagnosis was confirmed by the presence of bacilli or by positive subcutaneous reactions; 52 were positive to Lautier test, 41 to the v. Pirquet, and 31 to the Ligniere. The Lautier was positive five times when both the others were negative, but never negative when both the others were positive. The v. Pirquet was positive twice in contradiction to the other two, and negative five times. The Ligniere was never positive when the other two were negative but was negative 10 times when both the others were positive. In regard to the Lautier reaction, the varying results between 93 per cent. of reactions in his first series of 54 cases and 50 per cent. in his second series of 24 cases led him to doubt the value of this reaction.

Further Observations on Muscle Rigidity as a Physical Sign in Diseases of the Lungs and Pleura. A New Physical Sign in Diseases of the Chest.—Dr. F. M. Pottenger of Monrovia, Cal., said that in March, 1909, this phenomenon was described by him, and in this paper (to be published later) he wished to make further observations on it.

Progress and Changes in the Treatment of Tuberculosis During the Past Twenty Years.—Dr. Edward R. Baldwin of Saranac Lake, N. Y., said that many changes and some progress had been made in the past two decades. He called attention to the prevalence of the germicidal idea in therapy in the '80's, when creosote, sulphuretted hydrogen per rectum, oxygen, antiseptic oils, etc., were in vogue. The fatuous belief in germicides had never died out. He then spoke of the tuberculin furore and its collapse; later only a few daring ones continued its use. The disappointment was great among the mass of physicians. Cautious men became skeptical, but quacks throve. Then followed a reaction to less medication or therapeutic nihilism. It seemed a barren year that did not produce at least two sure cures for tuberculosis. The tuberculin treatment was replaced by the antitoxic theory, and again there was disappointment, for there had been great expectations. Research in this was even now going on, and prospects of a specific were not hopeless. He called attention to the former prevalence of belief in specific climatic virtues, to its modification, the growth of hygienic and sanatorium ideas, to better rationale, to the improvement in symptomatic treatment and management, of fever, cough, and hemoptysis, etc. Fresh air, feeding, and rest were important measures in the treatment of tuberculosis, but some had gone to extremes, and the home treatment was vaunted beyond reason. A reaction would again occur, in which climatic changes would receive its true valuation for the patients who most require it. The style of treatment of tuberculosis was like the style of hats—it changed with the seasons—but the majority had been dropped without sufficient trial. There was no doubt but that there was some value in tuberculin therapy. There had been much progress in surgical tuberculosis by means of the Bier method. There was much to be grateful for in the results that had already obtained. Much progress was on the whole to be noted and little of value had been lost.

Dr. Carroll E. Edson of Denver, Colo., emphasized the importance of a thorough and complete history of tuberculosis cases in making a prognosis. It was Hippocrates who said: "Prognosis was the summit of the art of medicine." Before giving your prognosis one should obtain the previous history, not only of the patient, but of the parents and even the grandparents. By so doing one would be amply repaid in the future care of these patients. The time was well spent and the knowledge gained would be to the patient's benefit. In their enthusiasm over skin tests they were likely to hear of curious things, and he reported the case of a man who went all over the country, having skin tests made, but neglected to have his sputum examined, in which were contained large numbers of tubercle bacilli.

Dr. Charles F. McGahan of Aiken, S. C., said that moving camps for tuberculous patients were all right if practical, but he did not think they were. With regard to cases of hemoptysis, he reported one case that died immediately and another case that died two days after its occurrence. Hemoptysis was less frequent in women than in men. When a woman got a hemorrhage she laid down, but a man would not take complete rest. There was nothing so good in cases of hemorrhage as complete rest. Dr. Pottenger's method was worth a great deal, no doubt, if he had demonstrated it to them; it required much tactile dexterity.

Dr. E. L. Shurley of Detroit believed that when hemorrhage occurred women were less frightened than men and showed more pluck, whether the hemorrhage was from the lungs or elsewhere. He believed that women had more courage than men in all walks of life.

Dr. Henry Lee Barnes of Wallum Lake, R. I., said that he had used the Lautier test in 100 cases of tuberculosis and in no case was he able to see any redness or anything that resembled a tuberculin reaction; in fact, there was no reaction at all.

Dr. De Lancy Rochester of Buffalo, N. Y., hoped that in a return to rational treatment they would continue to use tuberculin hypodermically. He got his enthusiasm from Dr. Trudeau a few years ago and in using small doses of tuberculin in suitable cases obtained good results. The reason the nuclein was in disrepute was on account of its being so painful. He said that one physician had used it by injection daily for eighteen months and the patient was virtually well. These were two very useful methods of treatment and he hoped that their use would be continued. With regard to the cough, he wished that they could devise some means of constant inhalation which would relieve it.

Dr. John W. Brannan of New York reported some experiences he had had at Sea Breeze, a hospital for surgical tuberculosis situated at Coney Island. Lanolin had little absorbent power and, therefore, he thought he would leave it out of the tuberculin preparation. The result was that the reaction appeared within fifteen or twenty hours; when lanolin was used it did not appear within two or three days.

Dr. A. Jacobi of New York believed lanolin to be an absorbent of the first class, but it should be used with a little water to get quick results. Increased resistance to the finger he believed was found in every case that was percussed where there was thickening underneath due to acute or chronic inflammation. With regard to muscle rigidity he called attention to this sign seen in hip-joint disease; the first symptom of hip-joint disease was a spasm of the muscles and the pain referred to the knee. With regard to the treatment of tuberculosis, he said that for eighteen years he had been using guaicol with splendid success. He also ordered arsenic and these patients seemed to grow fat on it.

Dr. Edward R. Baldwin of Saranac Lake, N. Y., said there was much confusion regarding the cutaneous or tuberculin test; it was not of such great value as a diagnostic test, but as a confirmatory test.

Dr. R. G. Curtin of Philadelphia called attention

to the different reactions that occurred from different preparations of the tuberculin.

Dr. James M. Anders of Philadelphia said that the duration of the fever was of more importance from the standpoint of prognosis than the degree of temperature. The pulse also was a splendid guide in the question of prognosis, but it should be borne in mind that the pulse was very much under the influence of the nervous system; the nervous element in many cases might explain the frequency of the pulse; in such cases it was not such a dangerous omen. In these cases digitalis, if used judiciously, would slow the pulse quite constantly, especially when used with nervines. He thought that Dr. Pottenger's article was one of great scientific as well as practical interest, although some of his explanations were perhaps open to mild criticism. The point he wished to make in his paper was that while fatal hemorrhage might occur in the female it was distinctly infrequent when compared with its occurrence in the male. He called attention to the importance of fresh air, diet, and rest in the treatment of tuberculosis; their increased knowledge of the value of rest in this disease, as well as proper feeding, marked a distinctive advance in the treatment of tuberculosis.

Dr. Herbert B. Whitney of Denver, Colo., spoke of cases of tuberculosis in which recovery had taken place; for ten years or longer patients would not cough or have any expectoration, yet when told to cough dry râles would be discovered.

Dr. Taylor of St. Paul objected to the idea of movable camps for the tuberculous patient; it was not practical. What these patients needed was rest, good food, and discipline. With regard to race, he said he had never seen a member of the colored race recover and he had seen but few Hebrews but what did recover.

Dr. F. M. Pottenger of Monrovia, Cal., believed that discipline was a very good thing. It would be bad for patients to look upon moving camps as a frolic; he did not believe they were practical. With regard to hemoptysis, he recalled two ladies who died of it, and probably ten or twelve men. It was a peculiar thing that these hemorrhages occurred in the early morning hours, or at midnight. If it was cold and turned warm, these patients spat blood; if it was warm and it turned cold, they spat blood; if there came on rain, they spat blood; bleeding depended upon meteorological conditions largely. He depended more upon the tactile touch in percussion than he did on the sound. He could not conceive of a pleuritis being present without this muscular rigidity.

Dr. James M. Anders of Philadelphia said that he had used guiacol for many years in the treatment of tuberculosis and in ascending doses, as they formerly used creosote. He thought that the use of guiacol increased the tendency to hemorrhage from the lungs.

Dr. Charles E. Quimby of New York said it was seventeen years since he read a paper before the association describing the pneumatic cabinet. The cabinet did to-day precisely what he claimed for it then. It did not produce hyperemia of the lungs; it produced a quantitative increase of the circulation through the lungs and lowered the blood pressure.

Climatology of the Northwestern States.—Dr. H. Longstreet Taylor of St. Paul read this paper, dealing with the climate of the sea coast, the mountains, the valleys, plateaus, and plains of the Northwest.

Climatology of the South.—Dr. Charles F. McGahan of Aiken, S. C., read this paper.

The Influence of Meteorological and Climatic Conditions on Metabolism.—Dr. John Benjamin Nichols of Washington, D. C., read this paper. (See page 471.)

A Diet for Every Day Use.—Dr. Horace D. Arnold of Boston presented charts to show the result of his efforts to put the regulation of diet on a practical basis. The quantitative regulation of diet was as important as the qualitative regulation. The basis of a scientific dietary was calculated on the nutritional value of food expressed in calories; they showed the total amount of nutrition in protein fats, and carbohydrates. In speaking of the principles of dietetics he said that the unit for the measurement of nutrition was the chemical heat-unit, or caloric, the amount of heat necessary to raise the temperature of one kilogram of water one degree centigrade. One gram of protein would produce 4 calories; 1 gram of fat would produce 9 calories; a gram of carbohydrate would produce 4 calories; and 1 gram of alcohol would produce 7 calories. With regard to nutrition for twenty-four hours, an adult required at rest 14 to 16 calories per pound; at light work, 16 to 18 calories per pound; at moderate work, 18 to 20 calories per pound. An average sized man required at rest 2,000 calories in twenty-four hours; at light work, 2,500; at moderate work, 3,000. Owing to the relatively greater surface in proportion to weight, the loss of heat was relatively greater in children and they required a higher number of calories per pound. The tables gave the composition of ordinary articles of food. The values were approximately only, but were sufficiently accurate for practical purposes. One table contained the articles of food which were most commonly employed. There were spaces for a summary of the nutriment in twenty-four hours. In the day record one column was for the total daily amount of each article of food used. In the next column was to be placed the corresponding value of each article of food, expressed in calories. A daily record of the number of grams of a given form of nutrition was often of very great value. For example, in nephritis the total daily grams of protein, and in diabetes the total daily grams of carbohydrates. Another column was for a record of the amount of water ingested daily. The daily records could be compared by glancing along the line.

Seasonal Influence on Suicides.—Dr. W. F. R. Phillips of Washington, D. C., in this paper stated that there was a regular rise and fall in the number of deaths self-committed, the greater number coinciding with the warmest part of the year, and the less number with the coldest part of the year. In midwinter there was the least number of self-inflicted deaths. The causes of self-murder he classified under two headings, the rational and the irrational. Under the latter, or true suicides, were to be included those who were tired of living and who had an extensive craving for or love of death. Here were to be included those with mental aberration, those whose act depended upon irresistible impulses, and a certain proportion of cases in which any slight shock would awaken unnatural impulses. The physical and mental instability of people furnished the true suicide. There were two suppositions regarding the causes; first, that based upon the accumulative irritability of the nervous system generally; secondly, that based upon the effect of annual variations, qualitatively and quantitatively, of the average daily diet.

A Note on Fresh Air in the Treatment of Acute Insanity.—Dr. Sanger Brown of Chicago read this paper, which was a plea for a more efficient system of ventilation in institutions devoted to the treatment of the insane, and also for outdoor treatment. Patients with acute insanity, aside from that which accompanied acute paresis, or where there were pronounced signs of mental deterioration, had a strong tendency to recover and the indications for treatment were to as-

sist nature in her restorative work. Every patient should be treated as an individual. He emphasized the importance of fresh air in the treatment of acute insanity and told how best it could be carried out. It was wonderful how patients acutely insane, noisy and wakeful, would become quiet when placed in fresh air and without the use of sedatives. They should be placed in an ample-sized room and where there was forced ventilation.

Diet and Climate.—Dr. W. M. Gibson of Utica, N. Y., called attention to the importance of the regulation of the diet in chronic diseases of the heart, blood-vessels, and kidneys, and to the great importance of a carefully selected diet for subjects of those disorders who would not, or who could not, seek relief from the depressing effects of a Northern winter. There was a great necessity of a close observation of the nutrition of persons of advanced life who wintered in the North, especially of those who manifested symptoms of cardiac and arterial degeneration.

Col. William C. Gorgas, U. S. A., who was introduced by the president, said that the work of the sanitary department in Panama had been kindly recognized by the medical profession in the United States and they had perhaps been given credit for some things they had not done. Manufacturing climate was a thing that was entirely new to him. His life during the past ten or fifteen years, dealing largely with tropical sanitation, had led him to minimize in his own mind the so-called paramount importance of climatic conditions in malaria and yellow fever. In the old days before the individual causes of these two diseases were known, one laid great stress upon climatic conditions, and thought that certain conditions of moisture and temperature were absolutely essential for the development of these two diseases; but when the true cause of these diseases was discovered this idea was minimized. As to protecting the men against the conditions met with in Panama, their health appeared to remain good in spite of the heavy rainfalls and heat; and it should be remembered that the conditions in the tropics tended to debilitate and pull down white men, although he could not state positively that they did. In Panama there were 8,000 Americans connected with the Commission and 12,000 in the Canal Zone, and on all these they had to keep an accurate tab. They belonged to a class of mechanics, and were of a higher degree of intelligence than the ordinary laborer and the death rate among them was very small; in fact, they appeared to be in better condition than they would have been had they been at their own homes. They were furnished good quarters. Connected with the Commission were the wives and children of these men, numbering 3,000, and their condition was equally as good as if they were home. It was surprising that the death rate among the women and children was even smaller than that of the men; there were four or five deaths per thousand among the women and children; he could not assign any satisfactory reason for this. He thought that too much stress was laid upon the debilitating effects of climate, but of course in dealing with such a comparatively small number of people one should not attempt to make any generalization in this direction.

Dr. Alton of Hartford, Conn., said that it was a mistake to attempt any generalization on the question of climate, and he called attention to the great variety of climates, and it was only by studying climate, especially that which was characteristic of small localities in large areas, that would bring them to the knowledge of the true place to send patients.

Dr. James M. Anders of Philadelphia said he was particularly interested in Dr. Nichol's paper on the subject of climate and metabolism. It was well recognized that climate was responsible for the various races and therefore it must have a tremendous effect upon bodily metabolism, but the exact effect of climate in this respect had not yet been determined. He was particularly struck with the practical bearing of the tables and charts presented by Dr. Arnold. His personal experience had shown him that the average physician was woefully deficient in his knowledge of dietetics. The effect of climate upon self-murder was very striking. Self-murder was perpetrated by persons perfectly sane and it seemed to him that the cases to be classed among the rational forms of suicides should have a better showing than in the chart presented.

Dr. Whitcomb of Norristown said they had been very much gratified by the results of open air treatment, night and day, at their institution at Norristown; in the acutely insane it was remarkable the rapidity with which they became quiet; many were subdued even quicker than if sedative medicines had been given.

Dr. Charles L. Minor of Asheville, N. C., said he did not believe in forced ventilation; this had been tried in large public institutions and had proven to be a failure.

Second Day—Saturday, June 5.

The Intravenous Administration of Strophanthin in Pneumonia.—Dr. A. K. Stone of Boston read this paper. In 1906 Fraenkel reported on the use of strophanthin administered intravenously, but the pain caused by its introduction was so great that it was abandoned. In cases of broken cardiac compensation the action of the drug was immediate. Strophanthin was a rapidly acting cardiac stimulant for use in desperate cases, where prompt results were desired. Dr. Stone said that one milligram injected intravenously would produce no evil effects and would have a prompt action upon the heart; a change for the better in these cases would occur in from five to fifteen minutes and would persist for from twelve to fifteen hours, and sometimes for several days. The blood-pressure would be improved. After giving a brief *résumé* of the literature on the intravenous administration of strophanthin and the dangers of its administration, he reported cases illustrative of its effects in collapse in pneumonia, in collapse following surgical operations, and in delirium tremens. A number of deaths had been reported as being attributable to strophanthin, but he thought that it was doubtful if it was the strophanthin that was at fault; any case of advanced cardiac disease, especially those cases in which strophanthin was indicated, might die suddenly. In the giving of digitalis by the stomach several hours might elapse before the cardiac action would occur and the patient might die before that, death occurring in spite of the digitalis, when in fact it was the cause of it by its delayed action. Again in some of these cases digitalis in frequent repeated doses might have been given prior to the giving of strophanthin and this might be a factor in cases of sudden death. Dr. Stone knew of eight cases of sudden death that had been recorded. In the introduction of strophanthin into a vein great care should be taken to get the solution in the blood stream. Any vein that was easy to get at could be used. Of course, failures in the use of this agent in cases of cardiac failure had exceeded the successes. In a series of pneumonia cases the use of the intravenous injection of strophanthin would enable a

number of the cases to be carried along until the patients were able to eliminate the toxin and get on the road to recovery. If the physician was on the spot when collapse occurred in these cases many lives might be saved. Dr. Stone did not advocate strophanthin as a specific in pneumonia by any means, but in certain cases of collapse strophanthin was capable of helping the heart do its work.

The Treatment of Pneumonia by Drugs, According to the Interpretation of Dr. Sajous.—Dr. J. Madison Taylor of Philadelphia read this paper, in which he stated that the crux of the whole matter of the treatment of pneumonia depended upon the management of the critical period. On or about the third day the reaction of the organism in its efforts to overcome the enormous quantity of toxins (specific and others) resulted in the production of an even greater amount of autoantitoxin in order to destroy them. This excess of protective substances became in themselves a source of danger, because of the large amount of adrenal secretion present. An enormous rise of blood-pressure followed in the already congested lung, which thus became overwhelmingly engorged. Hence the special danger of death by asphyxiation, a fatality which so often occurred at this stage. In the selection of remedies these pathological features should be kept in mind and counteracted. Creosote carbonate counteracted the congestion by causing dilatation of the arterioles throughout the entire body. The bromides also proved useful in assisting in the lowering of the blood-pressure and in counteracting congestion, yet without diminishing the antitoxic properties of the blood. Hypodermoclysis at this time was particularly useful and often proved life-saving by diluting the body fluids, enhancing osmosis and variously facilitating adrenal action, sustaining the alkalinity of the blood, promoting diuresis, and eliminating toxins and toxic waste. The use of physiologic salt solution as a beverage was indicated. The drugs cited were only types. Many others could be used which produced similar effects. Doses should be adequate in amount and given sufficient often to produce the desired results or they failed. All rational measures were likewise to be employed, open air treatment, etc.

The Treatment of Pneumonia and Its Variations in the Past Half Century.—Dr. A. Jacobi of New York reviewed the nature and treatment of pneumonia from the earliest days to the present. Interstitial pneumonia was a disease very frequently overlooked. There was the retracted chest, the bronchophony, the absence of cough, and of râles, etc. Cough was absent unless there was an accompanying bronchitis. There was dullness on percussion. In many cases this disease was mistaken for tuberculosis. Of the pneumonias there were now known as many as ten or fifteen varieties, and if one was looking for a specific for pneumonia he should have a specific for every one of the etiological factors. Treatment should be directed not to the pneumonia so much as to the individual who had one of the forms of pneumonia. The disease lasted a certain length of time and the best thing they could do was to keep the patient alive until the lungs were better. There were many things they might do for these patients. Strophanthin would save many patients that would have died without its use. If the circulation was slow, many mishaps might occur; if very slow thrombi might form in the vessels of the lungs, and they knew nothing that would dissolve thrombi. The prognosis should not be given as hopeless so long as there was anything to be done. A great many cases would recover without much treatment. But there were others where treatment, and prompt treatment, was required. For instance, take a patient in his third day of pneumonia with dilatation of the right heart, cyanosis, and beginning pulmonary edema; such cases were often given up, but they could be saved by venesection, thus enabling the right heart to contract again. These were the cases that responded to venesection, especially when it was combined with large doses of digitalis. He generally used the fluid extract of digitalis and such cases required as much as ten or twelve minims at once; in two hours he gave another dose; two or three such doses of the fluid extract of digitalis would very frequently save life. He said he was speaking only of the desperate cases. If the patient was left alone two, three, or four days, the heart would become weaker; he therefore insisted upon immediate stimulation with such agents as digitalis, sparteine, etc., from the beginning; but when the fifth, sixth, or seventh day was reached, with the pulse going up and becoming weaker, when the feet become cold and other signs of cardiac failure were present, then only large doses given subcutaneously would do good. He used caffeine for this purpose, both in adults and children, especially when there was pulmonary edema.

Indications for Venesection in Pneumonia.—Dr. De Lancy Rochester of Buffalo, N. Y., repeated an epigrammatic expression of an Englishman, which he thought gave the essence of the treatment of pneumonia: "Make the blood clean and keep it circulating." For this purpose relieve the toxemia and open up the emunctories. In a certain number of cases the invading bacteria apparently were getting the upper hand, and the toxemia was becoming profound, the temperature rising to 104°, 105°, or even 106°, with respirations 40, 50, or even 60, with flagging pulse, with coated tongue, sordes on the teeth, foul breath, carphologia, and subsultus tendinum, and something must be done and promptly to save life, and in such cases venesection gave striking results. The withdrawal of from 200 to 400 c.c. of blood was often followed by the recovery of the patient. He reported illustrative cases, but he cautioned against bleeding in these toxic cases when improvement had already set in; if one bled at that time there would follow an increase in the toxic symptoms and a fatal termination. The object of bleeding was to get rid of the toxic material. Sometimes enteroclysis of normal salt solution would be an aid. Another indication for venesection was in those cases of marked involvement of the lungs with marked toxemia, with a dilated right heart, and one that was unable to empty itself; in these cases, too, the results were often very striking. He closed his paper by stating again that bleeding was indicated in pneumonia (1) to clean the blood and (2) to keep it circulating.

A Report of Cases of Pneumonia in Colorado.—Dr. J. N. Hall of Denver, Colo., reported 250 successive cases of acute lobar pneumonia, studied especially as to the influence of altitude upon the disease. The mortality of this series was 42.8 per cent., but this was largely accounted for by the fact that all but 18 were seen in consultation, suggesting, of course, a grave class of cases. The mortality for the years 1903 to 1907, inclusive, for Denver was 172.0 per 100,000. The average for Chicago, Kansas City, Jersey City, New York City, Atlanta, Sacramento, Wilmington, and Taunton, Mass., for the same period was 183.3 per 100,000. In the mining communities of Colorado the rate was much higher; in Leadville it reached a proportion of 413 per 100,000. This was largely accounted for by the character of the population, the frequency of alcoholism, and especially the presence of

beginning miner's phthisis, although the altitude doubtless brought about cardiac failure and suffocative phenomena more frequently than at lower levels, and thus tended to increase the mortality.

Baths and Exercise in the Treatment of Heart Disease.—Dr. Robert H. Babcock of Chicago read this paper. He first considered baths, Nauheim baths, and after mentioning that it was Baeneke and the Schott brothers who drew the attention of the profession to the remedial virtues of Nauheim baths in acute and chronic endocarditis, outlined the principles underlying the same. Simple saline waters were soothing and quieting to the heart and hence at temperatures of 93° to 90° F. were indicated in cases showing considerable dilatation and weakness of the heart. These initial baths were not charged with carbonic acid, as a rule, or at least but feebly so. As the heart gained in strength and the circulation improved, the waters were charged more strongly with both chlorides of sodium and calcium, and their temperature was lowered from 90° to 87°. These baths were also strongly effervescent and now became powerful cardiac stimulants. In all the cases submitted to balneology after this method the reaction of the patient should be watched carefully, since these baths were cool and not hot baths. They were indicated in practically all forms of cardiac disease, except aneurysm of the aorta, or when there was pronounced fibrous mediastinopericarditis. They should be employed with care also in stenosis, and were of special service in dilatation from overstrain or chronic myocarditis. Exercises were of two kinds, the so-called resistance gymnastics elaborated by the Schott brothers and employed particularly in cases of pronounced cardiac feebleness with dilatation. The author now employed these resistance exercises but rarely, since he obtained better results from certain others, which consisted of active breathing movements, care being taken always by the gymnast that the breathing was diaphragmatic and in proper synchronism with the acts of inspiration and expiration. As the strength of the heart improved these respiratory gymnastics were supplemented by active movements of flexion, extension, and rotation of the extremities and trunk, these movements being assisted at first when the heart was weak and later performed by the patient alone, but in all cases were carefully supervised by the trained assistant to see that breathing was conducted properly and in harmony with inspiration and expiration. When these gymnastics were properly performed they slowed the pulse, improved its quality, lessened dyspnea, and reduced dilatation. They were especially suitable to cases of chronic myocarditis as seen in business men of full habit and usually with high blood-pressure. They might be applied with care, however, to cases of valvular disease, and in some children with small chests and hypertrophied hearts had accomplished most gratifying results. In all cases they should be supervised and controlled by the physician.

Dr. Charles E. Quimby of New York said that ten years ago he was disgusted with his own treatment of pneumonia and that of others and had never seen anything advocated in the treatment of this disease that had any good effect upon it, and, therefore, he thought he would try theory. The chlorides were retained, not because the kidneys were not able to excrete them, but because the system wanted them. Therefore, for ten years he had treated pneumonia patients with from ten to fifteen grains of sodium chloride with from six to eight ounces of fluid every hour of the twenty-four, with castor oil night and morning, and as yet he had not seen a case of pneumonia refuse to answer; he had not seen a single case with dry tongue or with delirium since he began this treatment. He said that he believed this treatment had helped; it certainly had done no harm, and he wished the members of the association would try it.

Dr. John W. Brannan of New York referred to the treatment of not only pneumonia but practically all diseases out of doors. He spoke of the testimony of physicians and nurses regarding the good effects of outdoor treatment of diseases and all were practically agreed as to the beneficial results following it.

Dr. Guy Hinsdale of Hot Springs, Va., advocated an abundance of fresh air and the use of water, ice, and compresses in the treatment of pneumonia. Treatment by outdoor air in outside wards, roof wards, etc., was of course one of the greatest helps in sustaining patients. The use of cold compresses over the chest and ice over the lungs was not only useful in adults, but in children as well. He presented pictures showing the balconies in three different hospitals. Dr. Lambert of Bellevue Hospital was not only impressed with this treatment, but thought there was nothing like it to shorten the course of the disease. Even children and babies were kept in the open air and did not require sedatives at night; their cough was apparently lessened, their appetite was improved, and their bowels were more regular.

Dr. E. L. Shurley of Detroit also spoke of the good effects of fresh air and water in cases of pneumonia; by means of osmosis there was a dilution of the toxins in the blood.

Dr. Boardman Reed of Los Angeles, Cal., said that the mortality from pneumonia to-day was three times as great as it was forty years ago and in those early days they used antiphlogistics and bleeding; therefore, careful and earnest thought should be exercised before condemning the old method. Dr. Rochester had called attention to the value of venesection; this was what saved the lives of so many of their forefathers. Why condemn it?

Dr. Carroll E. Edson of Denver called attention to the importance of increased frequency of visits to these patients. Cardiac stimulants were given, for instance, every four or six hours; it was just as necessary to have the physician's visit recorded as coming every four or six hours.

Dr. Charles F. McGahan of Aiken, S. C., acknowledged that he knew but little about the treatment of pneumonia. He had found in his experience that a certain set of pneumonic cases got well under a certain treatment and he felt encouraged; but with the next set of cases the treatment failed him.

Dr. Charles L. Minor of Asheville, N. C., said that the negro never ran the typical temperature course of pneumonia; the temperature was often subnormal. The cases he referred to were not those that were running on to tuberculosis. There was often no crisis. Convalescence in the negro ran a slower and atypical course.

Dr. John H. Lowman of Cleveland said that when the pulmonic second sound began to give out the interpretation was that the left heart was beginning to fail and this was usually the beginning of the end; more attention should be paid to the cardiac failure than to the disease existing in the lungs.

Dr. Herbert B. Whitney of Denver, Colo., said that his experience had shown that there was practically no difference in the course of pneumonia in Denver compared with those at the sea level.

Dr. De Lancey Rochester of Buffalo said that he did not wish to be understood advocating venesection in all cases of pneumonia. It was indicated only in certain cases. Among 400 cases that he had treated it had only been performed twenty times.

The Hygienic and Climatic Treatment of Arteriosclerosis.—Dr. Boardman Reed of Los Angeles, Cal., referred incidentally only to cases of arteriosclerosis due to syphilis, malaria, or other poisons from without which require the eliminant and antidotal drugs, and only briefly discussed those dependent upon physical, mental, or emotional overstrain which he believed required above all a cessation of the overstrain and more or less complete rest, often in bed, with massage, passive exercise, etc. He held that the great majority of cases of arteriosclerosis resulted directly or indirectly from an autotoxemia, and that the most prolific predisposing cause was an excess of food and drink ingested relative to the exercise taken, and the constipation arising so generally therefrom. The treatment recommended included, first of all, a reform of the bad habits, especially overeating and drinking, with lack of physical exercise; there should be a limitation of the food and drink to the actual needs of the system; the amount of liquids allowed should not exceed the quantity of urine passed, especially in those cases in which the heart shows failure of compensation. All the physical measures found useful in the maintenance of active circulation and elimination through the skin and in radically curing constipation should be employed. For these purposes he recommended various baths, especially the Nauheim effervescent baths, Swedish movements, and light regulated exercises, including particularly the resisted movements first practiced by the Schott brothers at Nauheim. He also recommended the various forms of electricity, such as general faradization, the high-frequency and Morton wave currents, massage, and vibration. Dr. Boardman Reed recognized three stages of the disease: (1) Presclerotic, in which the tension was variable but usually low; (2) one in which the heart was hypertrophied; (3) one in which there was failure of compensation. The treatment must vary with the stage as well as with the causes of the disease. He advised sanitarium treatment for the bad cases and for those having an unfavorable environment. A dry and equable climate suited such cases best and that of the Southwest, especially the regions in Southern California, not too far from the coast, were said to prove particularly advantageous.

Strophanthin in Dilatation of the Heart.—Dr. John H. Lowman of Cleveland, O., reported some concrete instances of the results of the use of strophanthin in cardiac dilatation.

Dr. De Lancey Rochester of Buffalo, N. Y., said that when one considered the subject of arteriosclerosis he should bear in mind that normally this change began in the arteries at about the age of thirty-seven, and from that time on one had more or less sclerotic arteries. When slight evidences of the disease appeared, it was very easy to advise a certain diet and mode of life, but it was exceedingly difficult to get the patients to live up to the rules and regulations given him. The regulation of the amount of food taken was a very important thing and in this he believed that Dr. Arnold's tables should be consulted. The use of salts to keep the tension down he believed to be better than the use of castor oil and similar eliminants. Alkaline drinks helped to eliminate better than ordinary water. Massage and proper exercises were of great value. Fresh air was as valuable in arteriosclerosis as it was in the treatment of tuberculosis. Warm equable climates were also useful. Any case of acute dilatation, especially in connection with arteriosclerosis, the patient should be placed in bed and be given milk, buttermilk, or a predigested milk diet. An agent of great value in his hands in the treatment of angina was tincture of aconite in large doses.

Election of Officers.—*President*, Dr. E. R. Baldwin of Saranac Lake, N. Y.; *Vice-Presidents*, Dr. James M. Anders of Philadelphia and Dr. H. Longstreet Taylor of St. Paul; *Secretary and Treasurer*, Dr. Guy Hinsdale of Hot Springs, Va.; *Council*, Dr. W. F. R. Phillips of Washington, Dr. E. L. Shurley of Detroit, Dr. Thomas Darlington of New York, Dr. Thomas D. Coleman of Augusta, Ga., and Dr. Charles E. Quimbey of New York; *Delegate to the Congress of American Physicians and Surgeons*, Dr. R. G. Curtin of Philadelphia; *Alternate*, Dr. Thomas Darlington of New York.

Malignant Empyema of the Antrum.—H. J. Davis has reported a case of chronic empyema of the antrum, which later became malignant and proved to be a fibromyxosarcoma.—*Proceedings of the Royal Medical Society.*

Scarlatina and Erysipelas.—Milhit and Vasseur have observed two cases of scarlatina complicated with erysipelas, a not infrequent association. It generally occurs late in the disease and accompanied by nephritis, which is often hemorrhagic. In view of the attempt to show that the streptococcus is the cause of scarlatina, it seems interesting to note that there is a partial vaccination against the streptococcus by scarlatina, sufficient to cause the general symptoms to be slight. There is only slight rise of temperature, and hearache; chills, and vomiting are not prominent symptoms. The erysipelas runs a mild course of eight or ten days, under the usual treatment, and is followed by a marked desquamation. The patient should be kept on a strict milk diet. The prognosis is not made worse by the presence of the erysipelas, as would be expected, the process being strictly a local one.—*Le Progrès Médical.*

The Influence of Cold on the Pathogenesis of Bacteriemia from Localized Pus Infections.—Francesco Stinelli has conducted experiments in animals to ascertain whether cold applied after inoculations with pus organisms would increase or diminish their effect. An injection of a sublethal dose of a culture of staphylococcus of low virulence, practised subcutaneously, causes rapid death of the animal if he be kept in a refrigerated atmosphere. In the control animals the same dose produced only local suppuration. Death did not depend on an increased virulence of the poison, but upon a lessened ability to resist the action of the germs. In the refrigerated animal, after a few hours, lesions were caused in the internal organs, producing transudation of serum into the peritoneal, pleural, and pericardial cavities. In the refrigerated animals a true bacteriemia occurred, while in the others the germs had not passed into the circulation. Inoculations into the veins had the same effects, the animals having a staphylococcemia with degenerative lesions of the internal organs, and multiple local metastases.—*Giornale Internazionale delle Scienze Mediche.*

Tarsalgia in the Puerperal State.—Tissier and Gautiez describe a certain kind of difficulty in walking which is experienced by women after labor, after a period of rest, more or less long, in which it would be supposed that the whole organism would be recruiting. This he finds to be due to a form of flat foot. The pregnant woman is obliged, in order to maintain her equilibrium, to walk in an unusual manner, on the fore part of the foot, instead of on the heel. This position allows of an atrophy of the posterior muscles of the leg, which do not function as usual. The weight of the body, instead of being supported by the mediotarsal bones, rests on the calcaneum. This bone becomes fatigued and sensitive. Another condition that tends to abnormal gait is that the woman is forced to walk with her feet wider apart than usual. The tibiae bear obliquely upon the astragalus, which pushes outward the calcaneum and favors the tendency to valgus. The general articular relaxation is a third factor in the production of flat foot. Now the muscles still further atrophy in the weeks of enforced rest, and when the woman comes to rise from her bed she experiences a true tarsalgia, a neuralgia that prevents her from walking easily. The plantar arch has lost its tone, sinks under the pressure of the body, and causes much pain in walking. The cure of this condition is easy and rapid; exercises of the muscles involved and a pad under the arch, or a flat-foot plate worn for a short time will bring about a cure.—*Réunion Obstetricale de Lyon.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of September 11, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	429	158
Diphtheria	188	23
Measles	88	6
Scarlet Fever	82	4
Smallpox	—	—
Varicella	11	—
Typhoid Fever	285	25
Whooping Cough	36	17
Cerebrospinal Meningitis	7	5
Malarial Fever	—	—
Totals	1,126	238

Acute Pulmonary Edema in Parturients.—A. Bonnet-Laborderie finds that acute pulmonary edema is an accident of pregnancy, of labor, of delivery, and immediately following labor. As to its production, in most cases it results from cardiac or renal lesions. But there are cases in which it occurs in which examination shows no cardiac lesions and no albumin in the urine. It is found that labor increases the pulse rate and the arterial tension, and that delivery does not at once reduce the tension on account of the removal of the fetal and placental vessels from it. The author recites the case of a healthy woman who passed through pregnancy and labor without accident, and after labor had a severe crisis of dyspnea, which cleared up entirely in twenty-four hours. She had neither heart nor kidney lesions. The author believes that we can only theorize as yet as to the causation in such cases.—*Journal des Sciences Médicales de Lille.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended September 10, 1909:

CLINICAL EXPERIENCE WITH CALCIUM LACTATE IN HEMORRHAGES OF THE UPPER AIR TRACT.*

BY W. K. SIMPSON, M.D.,

NEW YORK.

PROFESSOR OF LARYNGOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

THE control or prevention of hemorrhage from whatever cause or wherever occurring is of such vital importance that any measures which will be of assistance to us should be at once recognized and eagerly pursued. We cannot have too many resources at our command to meet the emergency. The danger of a hemophilic tendency should be ever before us, not only in instances of spontaneous bleedings, but also in its bearing on operative procedures, and no operation should be undertaken until we have *fully* contemplated the question of hemorrhage as to both its effects and control. The question of hemorrhage in operations takes its place in importance alike with that of shock and sepsis, and although we may feel secure behind the many cases in which none has occurred, yet that one unlooked for or unprevented fatal hemorrhage will always stand before us for daily contemplation.

The use of calcium salts for the control of bleeding has been employed for a sufficient length of time to make them a factor deserving profound consideration, their efficiency depending on the increase of the calcium content of the blood and consequent diminution of the period required for coagulation. This subject was first brought to the attention of the profession by A. E. Wright, of London, in 1891 and 1893,[1] since which time it has received a great deal of well-marked consideration.

My interest in the employment of calcium lactate began in December, 1905, in conjunction with Dr. John W. Coe, of New York, in the treatment of a hemophilic patient, who had been the subject of severe attacks of epistaxis for many years. All the known means had been employed, including chloride of calcium, suprarenal extract, and other constitutional measures, but, apparently, without any positive effect in controlling the hemorrhages for any length of time. I may here call attention to a most excellent article by Dr. Coe,[2] going at length into the treatment of a number of cases.

At this time we became familiar with the experiments of Wright and Paramore of London,[3] and Boggs,[4] in the use of lactate of calcium, and decided to give it a trial in the treatment of our patient. The result of its use became at once so positive in the control of the hemorrhages, and so far exceeded the effect of any previous medication, that I determined to use it not only with this patient, but in all subsequent cases where the prevention or control of hemorrhage was necessary, especially in the upper respiratory tract.

As the result of an extended experience since that time, I have come to the conclusion that we have at our command in the lactate of calcium a remedy which has a profound effect in many hemorrhagic conditions. I have employed it not only in non-operative hemorrhages, but also in hemorrhages associated with operations with an idea to their modification, if not prevention. The non-operative cases have been mostly those of epistaxis, and one case of hemorrhage of the lower trachea. Although it is well known that severe cases of epistaxis may yield to various measures, or cease spontaneously, still in certain of the cases under my care there can be no doubt whatever but that the immediate and continued control of the bleeding was due to the use of lactate of calcium.

In the patient referred to above, a physician of large practice and experience, the effect has been so marked that I think it deserves detailed notice. Prior to the use of lactate of calcium, apparently nothing but local measures, such as cauterization of the bleeding points within the nose, would have any effect, and this effect was but temporary, to be followed in very short order by frequently renewed and severe attacks of epistaxis. Since the use of the lactate, however, extending over a period of three and a half years, the hemorrhages are so controlled that they occur only at very long intervals, and then are due to some error in diet or accidental cause. Not only have the hemorrhages been controlled, but the character of the mucous membrane of the nose has undergone a very marked improvement.

During the many years of his treatment for epistaxis, the nasal mucous membrane was such that the slightest touch with a cotton applicator would bring on a profuse hemorrhage, but at the present time, when any necessity arises for manipulating the nasal mucosa, it can be done with comparative impunity, thereby assisting greatly in pressure control and in the cauterization of the hemorrhagic area; and the ordinary appearance of the nasal mucous membrane is much more healthy and normal. There can be no doubt that the control of the hemorrhage in this instance is due to the hastening of the coagulation time. This has been proven a number of times by Wright's tubes, wherein the period of coagulation has been reduced from 9½ minutes to 4 minutes, and in another instance from 9 to 3½ minutes.

In another instance, a young girl of 16, who was the subject of profuse nasal hemorrhages, and whose coagulation period was above normal, the use of the lactate produced a marked controlling effect and cessation of the attacks. With this patient also, complete blood examinations were

*Read at the annual meeting of the American Laryngological Association, held in Boston, May 31-June 2, 1909.

made, with the result of demonstrating the change in the coagulation period.

With a view of ascertaining whether lactate of calcium would control operative hemorrhages, I have made it a practice, when it is possible to do so, to administer it for three days prior to operation and three days or more after. The operations in which I have used the drug have been for nasal polypi, turbinectomy, various operations on the septum, and antrum operations—but mostly tonsillotomy and for removal of adenoids. In the intranasal operations, we do not have such a good field for observation in the control of hemorrhages by general measures, as the areas are immediately under direct control by pressure, but in certain cases, where no post-operative packing has been employed, there appeared to be less tendency to after-hemorrhage than in cases where it was not used. In the operations on the tonsils and adenoid vegetations, however, the conditions are entirely different, and afford a most excellent opportunity for observation in the control of surface hemorrhage, and it was upon this type of cases that my observations were concentrated.

As in cases of epistaxis, so also is the hemorrhage from adenoid operations and tonsillotomy a variable quantity, and it is difficult to get an exact basis for comparison, but from careful observations, extending over a large number of operations in clinic and private practice, one can make a comparison which is practical and conclusive. From the results of 75 cases of operation in private practice for the removal of tonsils and adenoids, in which the calcium lactate was given, I can say positively—if clinical observation amounts to anything—that there has been a controlling influence at the time of operation, but more especially in the *prevention* of secondary hemorrhage. Even more especially has this been observed in the cases under general anesthesia, where it is a recognized fact that hemorrhages at the time of operation are much more severe than when anesthesia is not employed.

Acknowledging the comparative rarity of severe immediate or secondary hemorrhages in these operations, it is a fact far stronger than coincidence that the *only* severe hemorrhages during the period under consideration that have come to my experience in a very large number of cases comprising private and many additional clinic cases, have been those in which the lactate of calcium was *not* given. These are five in number, one of which will serve as a marked illustration. The patient was a lad of 15, from the West Indies, upon whom the adenoids and tonsils were removed under ether. On the removal of the adenoids a most violent hemorrhage ensued, and after this had diminished somewhat, the tonsils were removed. This operation was followed by a still more alarming bleeding, reducing the patient to a very extreme condition, and necessitating active measures for its immediate control. The hemorrhage from the tonsils continued for several days, with variable severity, and it was during this time that observation was afforded for watching the coagulating effect of the lactate of calcium. As soon after the operation as possible, when hemorrhagic vomiting had ceased and medication could be retained, he was given an initial dose of sixty grains of the lactate, which was followed by thirty grain doses, four times daily, for several days, and more often when it was deemed necessary; and many times during its administration the blood could be plainly seen to coagulate in distinct firm masses, as it appeared on the surface of the tonsils. No blood examinations relative to the period of coagulation were made with this patient, but it was clinically evident that the lactate had a controlling influence. It was subsequently learned that a sister of the patient had nearly "bled to death" a year previously from a similar operation, there being probably a family hemophilic tendency.

There is no doubt, in this case, that the calcium lactate exerted a strong influence in the control of bleeding, and in the remaining cases of severe operative hemorrhages, in which it was not given till after the operation, there is every reason to believe that it modified greatly the subsequent course of the bleeding.

Relative to the dosage, I think it best in all cases to begin with an initial does of sixty grains, especially in the adult, children in proportion, and then thirty grains twice during the first twenty-four hours. In the non-operative and hemophilic cases, the drachm doses may be contained every morning and then every other day, until such time as there is improvement in either the bleeding or in the hastening of the coagulation, as determined by laboratory tests, the improvement to be maintained by occasional drachm doses. There are no hard and fast rules as to the amount to be given, but each case must be treated as conditions indicate. In operative cases, epecially for the removal of tonsils and adenoids, preliminary treatment should begin by the administration of the calcium lactate, when possible, three days previous to operation, and the drug should be continued for three days after; as these operations occur mostly in children, the dosage may be proportionately smaller, giving twenty grains, thrice daily, as an average. There seem to be no untoward symptoms arising from large or continued dosage. Coe[2] cites an instance in which, by mistake, a patient of 33 years was given sixty grains every three hours for six doses, with no ill effects, and our first-mentioned patient has continued with drachm doses almost daily, and sometimes twice daily, for nearly three and a half years; he is a close observer, and thinks that sixty grains is a maximum dose, and further states that in his own instance, a better effect is maintained in controlling the bleeding by omitting one or two days after a maximum effect has been reached. I may say here in passing, that at one time he discontinued its use for some while, taking up the serum injections in its stead, with the result of return of very severe hemorrhages, which were subsequently controlled by the resumption of the calcium lactate. It seems preferable to administer it when the stomach is free from food, *i. e.*, in the early morning and between meals. The lactate not being immediately soluble, the best means for its administration is to place the powder in a tumbler adding a small quantity of warm water, stirring thoroughly, then adding cold water up to a half or full glass. Attention has been called to some instances in which the inferiority of the preparation has minimized the results, and I consider the purity of the preparation a very important factor.

The object of this contribution has been simply to relate my own clinical experience and impressions, and I have purposely refrained from discussing the theories and variations relative to the subject of coagulation, the various modes of determining the calcium content of the blood, the period of blood coagulability, or the conflicting opinions concerning the efficiency of the calcium salts in the control

of hemorrhage; still it is interesting to note, and at the same time somewhat difficult to understand this diversity of opinion. Wright, in 1896[5] showed that after the ingestion of calcium chloride or lactate, the time of coagulation was shortened in hemophilic as well as in normal cases, mentioning in the same article an instance of a hemophilic in whom the result was negative, who failed to absorb the calcium, and the effect was not produced until a subcutaneous injection of the lactate was given, which finally controlled the hemorrhage from the gums, from which he suffered. A few days previously, however, an injection had proved inefficient. He advises against the subcutaneous injection of the chloride, and in reference to the lactate, it should not be injected in a stronger concentration than 1 to 20.

Wright and Paramore[3] state that calcium lactate causes increased rapidity of coagulation in twenty minutes and its maximum effect is reached within forty-five minutes, the effect being maintained for from four to seventeen days, and also that the effect of four grams, *i. e.*, about one drachm, is greater than a similar dose of the chloride.

Boggs[4] states that a distinct influence was noted on the coagulation after the taking of calcium lactate. In intervals of three days in which the calcium was omitted, the time required for coagulation returned to its former period, and was again shortened after the resumption of the calcium. Boggs concludes that, as it displays its efficiency in those patients in whom the time of coagulation is physiologically diminished, it may be regarded as a valuable remedial agent.

In another paper Boggs,[6] states that, after the normal calcium content of the blood had been determined, the dogs used in the experiments were fed with calcium lactate, in dose of 2 to 4 grams, twice daily, and after five days the animals were again bled and the calcium content determined. In both animals there was a marked and constant increase in the calcium content of the blood; coincident with this, there was an increase in the coagulability of the blood.

Hinman and Sladen[7] "consider the lactate the best calcium salt, the chloride being too irritating"; they had never seen the lactate cause the slightest gastric disturbance; and when given either by mouth, rectum, subcutaneously, or intravenously, it tends to shorten a delayed coagulation time. While it is requisite always to determine the coagulation time, there is no contraindication in giving the drug in normal cases.

R. Kobert,[8] in considering calcium salts as styptics, states that gram doses of calcium salts, including the lactate, given by mouth, enema, subcutaneous, or intravenous injections, in a 1 per cent. solution, cause immediate styptic effect in individual cases.

T. Addis[9] gives the following general conclusions as a result of a number of experiments: (1) The coagulation time of the blood is unaffected by the administration by the mouth of soluble calcium salts or of citric acid. (2) The amount of calcium in the blood is increased by the giving of soluble calcium salts and diminished by citric acid, but the increase or decrease brought about is considerably less than the degree of variation in the calcium content which is necessary before any appreciable effect is produced in the coagulation time. As these results were at variance with those of Wright of London, he gives a description of the apparatus used and discusses the difference between the two coagulometers, giving his reasons for relying on Blair Bell's calcimeter.

Geo. W. Ross[10] speaks of the favorable results, in the treatment of headaches due to insufficient blood coagulation, from the use of calcium salts, preferring the lactate to the others, it being more palatable, less nauseating, and often better absorbed.

Arthur P. Luff,[11] on the basis of numerous favorable experiences, recommends the use of calcium salts, especially the lactate, in fresh solution, in all diseased conditions which are associated with a lessened coagulative condition of the blood, and thereby a tendency to increased transudation of plasma through the capillary wall, noting the condition occurring in frontal headache with slight edema of face, eyelids, hands, and feet, also in urticaria, chilblains, and edema of the feet and hands not due to heart or kidney disease or venous obstruction. In his summary of 121 cases treated, 78 per cent. were cured, 9 per cent. were considerably benefited, and in 13 per cent. no good resulted from the treatment. In the 121 cases, no bad symptoms were produced by the administration of the lactate. Among a large number of other cases treated, not included in his paper, were only three cases where any unpleasant symptoms supervened which necessitated the withdrawal of the calcium lactate. These symptoms, he states, certainly pointed to some commencing thrombosis. In one case, there was a definite slight attack of venous thrombosis in the right calf; in the second, slight numbness of the arms and legs associated with tingling, and in the third case, tinnitus and deafness were produced. In the three cases the unpleasant symptoms rapidly subsided after the withdrawal of the calcium salt.

This question, of the danger of thrombosis from the use of calcium lactate, is frequently raised, but I have never seen any instances of it.

F. C. Ard[12] reports a case of profuse hemorrhage following tonsillotomy in which lactate of calcium was used with most satisfactory results.

Opposing views as to the efficacy of the calcium lactate are held by Dahlgren.[13] In two cases in which the lactate was administered by the mouth and by enema, there was a negative effect, both patients dying from secondary hemorrhage following operation for acute appendicitis. He concludes that in hemophilia, bloody operations should not be performed unless necessary for the prolongation of life, but states at the same time that a prophylactic treatment with serum, gelatin, and the calcium salt, may possibly prove of value.

W. E. Robertson, G. M. Ullman and A. A. Duncan,[14] also speak very strongly in opposition to the beneficial effects of calcium salts or any other means in controlling the period of blood coagulation. Their observations were carried out mostly in cases of typhoid fever, and they present a table of cases in corroboration of their views. Their article was read at a meeting of the American Medical Association in 1907, and in the discussion (Section of Pharmacology and Therapeutics) Dr. Lowe said that his investigations led him to believe that calcium salts had little value upon the coagulability of the blood. Dr. M. Solis Cohen says that Dr. Wright's statements seem perfectly true till one investigates them. He (Cohen) tested the coagulability of the blood in 50 cases, and was unable to corroborate any of Wright's statements relative to the clotting time in diseased conditions. Robertson pointed out that the chief value of work of this kind, if confirmed by others, was in warning us

against false sense of security in giving the calcium salts. This article was made the basis for including the calcium salts among "Pharmacologic fetishisms" by Barton,[15] who considers their use folly.

As the writer of this paper mentioned above, it is indeed difficult, in view of his own observations, to reconcile these diverse opinions.

My conclusions are:

1. Clinical experience shows that calcium lactate has a controlling influence in hastening the coagulation of the blood.

2. Its efficacy is more marked in hemophilic cases where the coagulation is delayed, than in cases of normal coagulation time.

3. Before operation, especially on tonsils and adenoids, careful inquiry should be made relative to any hemophilic heredity or tendency.

4. In suspicious cases the coagulation period should be determined before operation.

5. It is questionable, if not positively contraindicated, whether such operations should be undertaken in hemophilic cases, other than under the most extreme urgency.

6. In all cases of operations for the removal of tonsils and adenoids, calcium lactate should be given for a period prior to and after the operation, both for its possible effect in diminishing the immediate hemorrhage and in preventing secondary surface hemorrhage.

7. Of the calcium salts, the lactate is more positive in its results, is more agreeable to administer, and is less irritating to the stomach.

Concerning the Nature of Unilateral Pleuritic Effusion in Cardiac Disease.—Francesco Feliziani says that hydrothorax in cardiac and renal cases occurs only in the last stages of the disease. Unilateral effusions occur, however, only in the stage of good compensation, without hyposystolia. The appearance of this condition is slow and insidious, without dyspnea or other symptoms that would attract the attention. The cytological formula of the fluid is like that of pneumococcus pneumonia; there are present endothelial cells, polynucleated cells in large numbers, and a few lymphocytes. The fluid is small in amount, light yellow, and does not coagulate easily.—*Il Policlinico.*

THE THERAPEUTICS OF CALCIUM SULPHIDE IN RELATION TO SURGERY AND CONTAGIOUS DISEASES.*

By CLARENCE D. USSHER, M.D.,

VAN, TURKEY.

PHYSICIAN IN CHARGE OF THE AMERICAN MEDICAL MISSION AND HOSPITAL.

Where physicians are few and surgeons fewer, where civil hospitals are limited to the mission hospitals and operating surgeons to the one missionary physician, and no other is within from eight to fifteen days' journey, and assistants are none but uneducated natives who have never been beyond the confines of their own city, anything that can lessen the need of surgical interference or relieve the surgeon of the responsibility of major operations in purulent cases is most welcome. And where people have never heard of a microbe and know nothing of asepsis, infection, or segregation any remedy which will destroy infection and act as a prophylactic against contagious diseases is a boon. A perusal of books on Materia Medica and Therapeutics must impress one with the fewness of known positive remedies and the multiplicity of drugs of which we know little.

Calcium sulphide seems to be one of the drugs of which leading authors know or believe little. To us in our isolated Mission Station it has proven of untold value and we believe a knowledge of our experience may help to establish the efficiency of a much neglected drug and furnish a remedy for diseases heretofore beyond our control.

At the risk of arousing antagonism and incredulity at the outset, but with the hope of fixing attention, I propose to make first a bold statement of what we believe to be facts and then to follow it with case reports and illustrations showing what has led to these conclusions.

There may naturally arise a query as to credentials when any one presumes to speak authoritatively. My own use of calcium sulphide dates back to 1894, when under the advice of Dr. A. M. Wilson of Kansas City, Mo., I prescribed it in cases of purulent otitis media and furunculosis. In these cases it worked like a charm, as it did also in series of carbuncles on my own neck, one of which with thirteen openings had already run six weeks after free incisions and touching wtih phenol, and appeared likely to continue indefinitely. A few days of calcium sulphide stopped the discharge and dried up the other foci around it.

Our field of labor for the last ten and one-half years has been in Eastern Turkey, between five and six hundred miles south of the Black Sea, and for the past nine years at Van, a city of about 50,000 inhabitants, the ancient capital of Armenia, and situated at the same latitude and altitude as Colorado Springs and with similar climatic conditions.

The district from which we draw our patients and in which we have the only civil hospital, is larger than the State of New York and has a population probably in the neighborhood of two million. The immediate base for our observations is a hospital with 50 beds (where we have had more than 70 patients at one time), a dispensary with in and out-patient departments, where we gave in 1907 more than 24,356 treatments and made 1,207 visits

*Prepared for presentation to the New York Academy of Medicine in April, 1909, but not read owing to the absence of the author.

in homes, and in addition to these we have had the medical care of orphanages with more than 500 boys and girls as well as oversight of schools with about 1,000 scholars.

Having been unfortunately very much alone, we lack the corroborative testimony of other physicians, but my own observations and those of my dispensors and nurses persuade me that at least in Van and probably anywhere else:

1. Calcium sulphide will disinfect and bring about absorption of even large quantities of pus and will prevent pus formation. For some reason, possibly non-absorption or age of drug, it is not always specific.

2. Calcium sulphide appears to be a specific cure and anti-infectant as well as prophylactic in typhus exanthematosus, variously known as famine fever, prison fever, and ship fever.

3. Calcium sulphide appears to be an efficient prophylactic for scarlet fever and distinctly modifies scarlet fever and measles.

4. It prevents pustulation, pitting, and secondary fever in smallpox, very decidedly shortens the disease, and appears to lessen if not entirely destroy the contagion, and also to act as an efficient prophylactic in the absence of vaccination.

In the beginning perhaps I should say it has always been our rule to evacuate pus wherever we found it. Sometimes, however, this is not feasible.

Now let me give a few cases in illustration of these points.

Suppuration.—Case 1. A. S., female, aged 26, married, debilitated, mother died of tuberculosis. In ill health several years. Suspicion of miscarriage. Severe pain in left inguinal region for several days and growing worse. Frequent sweats, chills and fever. Examination revealed what appeared to be an abscess of the left Fallopian tube about 3 inches in diameter. Family refused immediate operation and entreated that medical means be used. Prescribed calcium sulphide, one-half grain, every two hours. This caused vomiting and was reduced to one-quarter grain every two hours, which was well borne. Within 24 hours improvement was marked, pains steadily decreased and symptoms of pus absorption subsided. The tumor gradually contracted and in two weeks had disappeared.

Profiting by this experience I have tried the same treatment in many similar cases with gratifying results. In the succeeding five cases I tried it with fear and trembling, but seeing recovery where experience seemed to say that the knife or death was the only alternative, I have gained confidence and now for five years have made it almost a routine practice.

Case II. G. K. male, 47 years. Periosteal abscess of left shoulder with caries of acromion process and pus burrowing in several directions. Operation performed and apparently all necrosed bone removed. Patient did well for two weeks, but when about to leave the hospital another abscess formed which discharged about 210 cc. of pus daily from under the scapula. Irrigations and injections of iodoform emulsion, ether-iodoform, and other things seemed only to increase the pus discharge. Calcium sulphide in one-fourth grain doses was given first hourly, then every half hour, but the pus increased rather than diminished till we gave half a grain every half hour throughout the 24, and then the pus ceased as if by magic; the sinuses closed and the patient was well in a week and has continued so for three years.

Case III.—Victoria ——, girl, age 12, tuberculosis; had severe pain in the lower abdomen and especially in the vagina; there was a large indurated mass surrounding the rectum, very painful to the touch, but fluctuation was not perceptible; pus temperature, rapid emaciation, anorexia, and inability to retain any but small quantities of food. Calcium sulphide was badly tolerated and frequently caused vomiting in ¼ gr. doses every two hours, but the symptoms were slightly ameliorated for a few days, followed by septic peritonitis and death in a few hours. Post-mortem revealed 1½ pint cavity of foul smelling necrosed tissue back of the rectum and burrowing into the sacrum; very thick inflammatory wall about the rectum and vagina. This patient was not materially helped by calcium sulphide.

Case IV, being in the hospital at the same time, with identical symptoms minus tuberculosis, an operation was performed and the cavity drained through the vagina. Patient was discharged apparently cured, but returned in seven weeks with a recurrence of the symptoms. Calcium sulphide ½ gr. was administered every half hour when awake and, as saturation showed, was reduced to ¼ and then 1/6 gr. every two hours for two weeks. The patient was emaciated and the appetite was poor, but even ½ gr. every half hour did not seem to affect the stomach. Recovery was uneventful and no recurrence in 1½ years.

Turkey, in common with other parts of the world, was afflicted last year with the grip accompanied by many cases of otitis media and subsequent otorrhea. When we used calcium sulphide, the ear symptoms subsided rapidly and there was no pus discharge, whereas severe pain and purulent discharge was very general among those who did not use calcium sulphide. Did time permit, I could cite dozens of cases of otitis media, of localized empyema, furunculosis, appendicular abscess, and perityphlitis apparently demanding the knife but cured by calcium sulphide. I might also cite a number of cases in which it was given as high as 1 gr. every half hour with apparently no beneficial results.

Typhus.—Four years ago, as a result of starvation and overcrowding, typhus exanthematosus, variously known as famine, ship, or prison fever, broke out in very virulent form in Van and spread with alarming rapidity, carrying off the rich as well as poor. One of our much beloved foreign associates and one of our leading native teachers as well as some orphans and many in the city outside of our premises succumbed to the disease. The poor were herded four or five families in a room with earth floor, insufficient fuel, almost no windows, and those and the doors kept tightly closed because of severe cold. Many had been living for months on bread made of the bran and the dirt sifted from the soldiers' flour, or the husks of linseed left from the oil press, and some on bread made of ground grape seeds and skins left from the wine press. I have visited rooms with as many as fifteen individuals lying sick on the floor, and known as many as four deaths a day from one house. Our Mission Circle lost one member and our boys' school a valued teacher. The disease got into our orphanage with about 450 boys and girls. Our hospital was crowded with typhus cases of a severe type.

From my books on Therapeutics and Practice, Wood & Fitz, Hare, Quain, and others, I could get little more help than "treat the symptoms as they arise," "there is no known remedy which distinctly

modifies the disease," and this from the best of authors. Too late to save a beloved friend who had developed thrombosis and abscess in the brain, in the agony that comes to every true physician at some time, and especially to one compelled to care for his own loved ones when all his skill proves vain, I sought the source of all wisdom, The Great Physician, and it seemed as if a voice spoke, "Use calcium sulphide." Rising from my knees, I went to the hospital, where several patients were apparently near death; others had just been brought in; one of the nurses had contracted the disease. Three patients in dying condition were selected and given calcium sulphide ¼ gr. every two hours, and in less than twenty-four hours the fever was gone and the patients were convalescent. For some days other lines of treatment were continued with other patients without marked improvement. Then calcium sulphide was given to five patients in various stages of the disease with the same result as the first three. After this it became routine to give calcium sulphide to every typhus patient, both in the hospital and in private practice. There were hundreds of cases in which to test it. Soon it became apparent that in houses where patients used calcium sulphide, no others contracted the disease. In the hospital where we had only between forty and fifty beds, we were compelled to put typhus patients alongside typhoid, pneumonia, pleurisy, malaria, and surgical cases. The same few nurses had to care for all. We have no contagious disease hospital. One-quarter grain calcium sulphide three times daily proved an efficient prophylactic. With the exception of a night nurse mentioned above and the superintendent, neither of whom took calcium sulphide as a prophylactic, no one in the hospital contracted the disease. The superintendent began taking calcium sulphide the third day of her disease with a temperature of 106.5° and in twenty-four hours her temperature was normal. So far as known but two patients succumbed after using the drug and they both began taking it when in a dying condition, with severe lung and bowel complications. Hence calcium sulphide appears to be as near a specific for typhus exanthematosus in Van, as can be looked for, and we hope climatic conditions elsewhere will not be found to modify its results.

Scarlet Fever.—In the summer and fall of 1906, an unusually severe epidemic of scarlet fever swept over Van and its neighborhood, having progressed southward during a period of eighteen months from Erzroom. The disease had been unknown in Van for twenty-three years, hence susceptibles were many and immunes few. It was estimated that from 12,000 to 20,000 cases occurred and from 1,200 to 2,000 deaths or more. Moslems carefully concealing their death records and depending on "Kismet" for treatment, their graves were many. We managed to keep the disease out of our orphanages and homes till October, when it began in a most virulent form, carrying off two of our older boys within thirty-six hours. Then our oldest daughter was taken sick. After the usual incubation period, six or seven more boys took sick. Then the calcium sulphide idea occurred to me and I ordered my pharmacist to make 3,000 ¼ gr. pills and give them to the orphans three times daily, the larger boys or company leaders to be responsible for their companies of forty. Five companies remained free for three weeks but the sixth company had case after case, between fifteen and twenty cases occurring in that one company of forty boys while others remained immune. Investigation developed the fact that the company leader had refused to give his boys the pills. They were compelled to take them, and the epidemic stopped in that company. A little later about forty mild cases broke out among the other boys who had taken calcium sulphide for about one week, three weeks previously, and twenty or more girls in the girls' orphanage developed scarlatinal sore throat. Persistent calcium sulphide treatment all around stamped out the epidemic and greatly modified the disease in those who had it.

Of our 450 children none had even been exposed to the disease before this epidemic. Presumably, and judging from the epidemic in the city outside of our premises, four-fifths were susceptible, whereas less than one-sixth of our orphans contracted the disease and most of these had no symptoms other than sore throat and desquamation. Three boys who showed no symptoms developed scarlatinal nephritis and albuminuria, which was the cause of the majority of deaths in the city. Spirit of turpentine proved our best remedy for the albuminuria. When our supply gave out, we used the oil of turpentine with the same good results; 3 to 9 drops t.i.d. in milk. The same prophylactic value of calcium sulphide was proven in the homes about us.

Smallpox.—November 3, 1907, a girl was brought to the hospital from the German orphanage well broken out with variola just passing from the umbilicated vesicular to the pustular stage; a fairly thick eruption but discrete. Pustulation and secondary fever had begun before saturation with calcium sulphide was complete, but then ceased immediately. Less than quarter of the vesicles pustulated, secondary fever subsided in a few hours, and in four days (November 7) the patient was sitting up asking to go back to school.

November 8 the superintendent of the German orphanage wrote me that she thought that one of the girls had scarlet fever. I saw her some hours later lying in a small room with five other girls, two of whom had pleurisy, one incipient pneumonia, and two malaria. One of them had had smallpox, none of the others had even been vaccinated. This girl with supposed scarlet fever was well broken out with confluent vesicular variola. She was removed at once to the hospital, saturated with calcium sulphide, and given daily antiseptic (sulphonaphthol) baths, as is our custom. There was no pustulation, no pitting in either case and in the confluent case no secondary fever. The five exposed girls were given calcium sulphide and none of them developed the disease, though two other girls in the orphanage, not so much exposed, did develop it.

We have had dozens of cases to treat in their homes and even where red curtains were not used, but calcium sulphide was, there has been no pitting. The nurse who cared for our smallpox cases had not been vaccinated nor had had smallpox. We had no vaccine and are 1,000 miles horseback travel from the nearest supply. The only safeguard for our nurse was ¼ gr. calcium sulphide every 3 hours. She and many others not otherwise protected did not contract the disease though much exposed. This of course proved nothing, but strongly suggests the possibility of calcium sulphide being a prophylactic for variola and kindred diseases, and valuable were vaccine is not obtainable.

In conclusion I would say the case reports herewith given are mostly of adults. I have found children sometimes requiring fully as large doses as the

most resistant adults and tolerating them perfectly; and I have found other children of the same age respond to even 1/20 gr. every two or three hours.

I believe that the efficiency of calcium sulphide in pus cases is due to sulphureted hydrogen liberated in the blood and acting as a germicide; hence the preparation used should be fresh, and strong in that element. It loses its effect it left open to evaporate its odor. Many of the preparations on the market seem worthless.

The dose varies according to the patient and seems more dependent upon constitution than upon age or body weight. Our rule is—small doses frequently repeated to effect, then enough to continue effect. The physiological effect of calcium sulphide saturation is the odor of sulphureted hydrogen from the skin and breath, not belched from the stomach.

Typhus exanthematosus is practically unknown here, but frequent in Europe and Asia. With the hospital facilities and surgical skill throughout America, purulent conditions may not trouble you as they do us, but scarlet fever and smallpox terrorize a large portion of the population of America and cost both Federal and Municipal Governments large sums for quarantine and care, to say nothing of the disturbance of business and loss of valuable lives. Calcium sulphide merits the most careful and thorough study by every practitioner and student in the land.

THE CLINICAL SIDE OF DISEASE IN THE PHILIPPINE ISLANDS.*

By THOMAS W. JACKSON, M.D.,

MANILA, P. I.

MEDICAL RESERVE CORPS, UNITED STATES ARMY.

I HAVE been much impressed during the past few years by the wealth of clinical opportunity that exists for men actively engaged in professional practice in the Philippines. Not alone is the amount of material for clinical study very great, but the distribution is very general and the variety is certainly extensive. Doubtless, in our search for the unusual things, in our consideration of the various problems of medical and sanitary administration and our pursuit of disease organisms in the laboratory, we pass by many cases of great clinical interest, which in less opulent fields of medical work would be eagerly sought and utilized for instruction purposes. While the hospitals and the medical school are doing this for the medical student we should make greater use of this material for our personal and individual improvement. In Manila, the San Lazaro, Bilibid, Civil, University, San Juan de Dios and Military hospitals afford an opportunity for most valuable post-graduate instruction. In provincial regions the material is less easily accessible, but there is no community in the archipelago where the establishment of a modest dispensary would not reveal a valuable amount of material for self-instruction. Such work would not only be helpful to the observer, but special diseases would be of great statistical value.

For my own part, I regret the waste of the clinical opportunity about me quite as keenly as I appreciate the cases which I have been permittted to see and study. During the past two years I recall having seen or treated the following tropical and general diseases and doubtless this list is not complete. Many, but not all, of these cases have occurred in military organizations, and the outside field must certainly be even richer. As my memory serves me I have seen cholera, beri-beri, dengue, dysentery (amebic and specific), leprosy, malarial fever (tertian, quartan and estivo-autumnal), malarial cachexia, ankylostomiasis, filariasis, bilharziosis, tapeworm, both large and dwarf (tenia saginata and tenia nana), whip-worm and ascaris infections, trichphyton infections of sevaral varieties, erysipelas, pemphigus contagiosus, yaws, smallpox, syphilis, pneumonia, pleuritis, influenza, typhoid fever, rheumatism, cancer, tuberculosis, nephritis, aortic aneurism and various heart diseases, amebic liver abscess and hepatitis without abscess, and appendicitis. When one adds to this list gunshot wounds and fractures, major and minor surgical operations, obstetric and gynecologic cases, insanity, and organic and functional nervous diseases, and a host of gonorrheal and chancroidal cases with complications, it must be admitted that medical experience here, if anywhere, is cosmopolitan.

I desire to make a few observations, with practical bearings, resulting from this experience and from the experience of others, either verbally related or reported in print.

Typhoid Fever.—Within the past two years inquiry into the prevalence of typhoid fever has led to a modification of the belief that the disease is a rare one in the Philippine Islands. It has been found to exist among both natives and whites, and to play a part of some importance in certain localities. The Surgeon General's Report for the Army for 1908 shows that the rate of incidence for the Philippine Islands per thousand men (white troops) was practically the same as for the United States (3.50 for the Philippine Islands and 3.53 for the United States), and the latest quarterly report of vital statistics for Manila (July to September, 1908) shows that thirty-three deaths from typhoid fever, all among Filipinos, occurred during these three months. Investigations by medical officers of the army show that the disease is also prevalent among the natives of the southern islands. Various departures from the classical types have been noted, but in the cases observed by me there were no specially noteworthy differences from the disease as seen in various parts of the United States and in Cuba. In the southern islands cases were reported showing deviations, both as to type and as to delayed response to the Widal test, but the modern conception of typhoid infections is more elastic than formerly and contemplates less dogmatic views as to fever curves and symptoms, while cultural and technical factors still enter into serum diagnosis.

A closer study of our cases of continued and remittent fever, with the possibility of enteric fever in mind, is therefore appropriate under the circumstances.

Cholera.—Concerning cholera I have little to say as we are soon to have the opportunity of studying valuable reports from those actually engaged in cholera work during the recent epidemic. But I cannot refrain from quoting and indorsing the following paragraph in the Third Quarterly Report for 1908 of Acting Director of Health McLaughlin. Dr. McLaughlin says: "However, cholera may be expected in the Philippines until provision is made for thorough organization of the provincial districts under trained men, the employment of local health

*Read by title at the sixth annual meeting of the American Society of Tropical Medicine, held at the United States Naval Medical School, Washington, D. C., April 10, 1909.

officers properly instructed and supervised, and the education of the people as to the cause of the infection, as to cleanly habits, and the proper disposal of feces."

Personally I am inclined to wonder whether we have not committed an error in placing our sole reliance upon the laboratory diagnosis of cholera. In the report just quoted, Dr. McLaughlin points out the fact that the interval between the January, 1908, epidemic and the reappearance of epidemic cholera in Manila in July, 1908, was bridged over by a series of cases in February, March, April, May and June, which clinically resembled the true disease, some cases proving fatal in a few days, yet negative bacteriologically, so far as the agglutination test was concerned. Few medical men in Manila doubt that these interim cases were cholera cases, negative laboratory reports to the contrary notwithstanding. In other words, cholera was present during every month. I am inclined to believe that the clinical diagnosis of cholera in these cases should be accepted and that the treatment, so far as isolation, disinfection and supervision of contacts is concerned, should be the same as in the bacteriologically proven disease, especially in the light of Manila's unfortunate experience and the difficulties which attend the fight here. I am sure that no one will interpret this view as indicating a disregard for laboratory methods and exact diagnosis. Difficulties of technique and variation of agglutinability of the organism are recognized as existing, particularly during periods of quiescence of the disease. During the active period of an epidemic, Manson's law should be remembered. He states that "it may be laid down that epidemic diarrhea with a case mortality of over fifty per cent. is cholera."

Self-deception as to the non-existence of Asiatic cholera in Manila and the provinces can only result disastrously. The official report of the Acting Director of Health for the Third Quarter, 1908, gives 673 cases of Cholera, with 458 deaths for Manila, and 17,619 cases, with 11,115 deaths from cholera for the provinces outside of Manila for the three months reported.

Dengue.—Concerning dengue, a disease which plays no part in the mortality statistics of the Philippines but figures distinctly in the morbidity among both natives and whites, there is naturally and properly much interest. This disease deserves closer attention, especially from the side of diagnosis and prophylaxis. During the past year (by reason of my station at Fort McKinley, where the disease prevails) I saw many more cases than in the previous twelve months, and I appreciate, more than ever, the difficulties attendant upon the diagnosis of the numerous sporadic cases, some of them atypical, which occur. In the midst of an epidemic the diagnosis by exclusion and by the direct method is not difficult in the great majority of cases, but in the isolated cases, constantly occurring, considerable diagnostic care is called for. As is well known the diseases which dengue most resembles in this latitude are malarial fever and influenza. From the former it may be definitely differentiated by microscopic blood examinations, but it should be remembered that a single negative blood examination is hardly sufficient to exclude malaria, as the parasites may be difficult to find under certain conditions—for example, owing to their small size immediately after sporulation or owing to their relative scarcity in the peripheral blood in certain stages of infection with estivoautumnal organisms. Three negative examinations of blood within forty-eight hours, however, will ordinarily suffice to exclude malaria.

The cases of dengue which, probably, most resemble malarial attacks are those relatively infrequent ones with single febrile periods, and the absence of the eruptive feature. A dengue case terminating its febrile course with a critical drop in temperature at the end of twenty-four or thirty-six hours will sometimes resemble malaria rather closely, but the severe pains and aches of dengue are not often simulated. The essential type of dengue, however, is a two-period fever in which the first period is sudden of onset, brief, and followed by an intermission or a marked remission; while the secondary fever is marked by a terminal rash, either distinct and striking, or faint and evanescent. This secondary period lasts for upward of forty-eight hours. The important diagnostic features of dengue, then, are the history, fever curve, pains and eruption.

In exceptional cases dengue attacks individuals infected with malaria. A puzzling symptom-complex may result under these circumstances.

The occurrence of influenza in the Philippines has not received much attention heretofore, but I am inclined to believe that cases occur, not infrequently, and that we must discriminate between this disease and dengue. The resemblance is well known and need not be dwelt upon here. I have recently seen more than a few cases which were clinically indistinguishable from influenza; marked by fever, catarrhal symptoms (expressed by coryza, pharyngitis, tracheitis, bronchitis and sinusitis), and general aching pains throughout the body. The temperature curves in these cases were certainly not those of dengue, and the catarrhal symptoms were prominent. In the United States these cases would be pronounced influenza without hesitation.

There is no good reason why influenza should not occur here, or why the influenza bacillus should not be freqnently imported into these islands, while the excess of sunlight and the universal open-air life led by the people—the two most discouraging conditions of existence for the influenza bacillus—will readily account for the absence of the disease in the epidemic form. Influenza occurs in Calcutta and elsewhere in India in December, January and February.

Without desiring to devote too much attention to dengue I would like to give a few of the conclusions reached by the Dengue Board at Fort McKinley, during 1908.*

The board, in brief, found that dengue has been present at Fort McKinley continuously since July, 1906, and that it has cut a decided figure in the sick report of the post. It confirmed the opinion that the disease is not contagious and tentatively accepted the finding of Craig and Ashburn that the disease is communicable by the mosquito *Culex fatigans*.

This mosquito has been constantly present, and during many months has been present in greater numbers than any other mosquito. It also concluded that the disease is preventable, in military posts, theoretically at least, and that it is entirely practicable to reduce the number of cases to an inconsequential one by the destruction of mosquitoes. It is interesting to observe that Sir Patrick Manson, in a recent address, gave his endorsement

*This Board was made up of army medical officers, and consisted of Drs. Boyer, Conner, Gapen, and myself.

to the view that the mosquito is the carrier of dengue, and stated that, "Given a patient with dengue, or with yellow fever, and you may inhabit the same room with him without risk of infection, if adequately protected from mosquitoes."

Individually, as clinical observers, we noted the symptoms of afflorescence of the bucal and pharyngeal mucosa, and of inguinal adenitis, or at least enlarged inguinal glands, in many cases, as well as all of the generally accepted symptoms of dengue.

In those cases in which leucocyte counts and differential white blood counts were made the total leucocytes were usually reduced and the lymphocytes were relatively increased.

In some hundreds of blood examinations of dengue patients no organisms were demonstrated other than a few malaria parasites.

Dysentery.—Concerning the clinical classification of tropical dysentery and its treatment I wish to express a few ideas only—the results of observations of this important group of diseases. I find the classification of tropical dysentery into bacillary and amebic varieties to be feasible and practical and, on the whole, quite satisfactory. Under the bacillary division I would expand the grouping to include some milder types of dysentery than the acute epidemic specific dysentery of Shiga (these subtypes due, perhaps, to variant strains of Flexner's or Shiga's organism), as we doubtless have true infections with *bacillus dysenteriae* which find expression in comparatively mild manifestations, both as to cases and as to epidemic occurrence. If the agglutination test be desired the test organism used should be grown from the stools of coincident cases, *secundem artem*, rather than from a laboratory strain of indefinite age or descent.

The occurrence of a few amebæ in the stools of acute dysentery cases does not necessarily indicate that the infection is amebic and not bacillary. While most of us are willing to admit that we are unable to distinguish between pathogenic and innocent entamebæ, and while we believe that all entamebæ in these islands should be regarded as potentially pathogenic, there is not, in my opinion, sufficient evidence to warrant us in pronouncing every case of dysentery with ameba-containing stools as one of amebic dysentery, pure and simple. On the contrary, I believe that a few amebæ may often be found, and are found, in the stools of patients with bacillary infections. And just here the clinical circumstances and aspects should be helpful. If it be remembered that bacillary dysentery is essentially an epidemic disease of acute onset, with a short incubation period and a more or less self-limited course; and that amebic dysentery usually begins as a moderate diarrhea, the stools at first being mucous in character and gradually becoming bloody, and that it is essentially chronic, with a marked tendency to relapse, there should be less confusion. It should also be remembered that fever may be absent in both diseases, although it is usually present in acute infectious dysentery of severe type.

Treatment.—In the past year or two, in Manila, there has been manifested some disposition, by a few men, to depart from the rather general agreement among Americans as to the treatment of amebic dysentery, which was reached in Manila and San Francisco and elsewhere in the United States, in the days when the military hospitals treated hundreds of cases of dysentery where they now treat tens. The empiric doctrine of "Ipecachuana for dysentery," much favored by British practitioners, has developed some exponents here. Personally, I have reviewed my opinions, formed in the old days when material for observation was most abundant and interest was keen, with a particular desire to find in ipecac the specific curative qualities claimed for it; but I confess that I have been unable to find them, and that I still believe that ipecac is not a specific for amebic dysentery. In my service in the medical wards at Fort McKinley during the past year I tried, impartially, the ipecac treatment and the local treatment, with colonic flushings and irrigations with amebacide solutions. The results were distinctly in favor of amebacide solutions. In cases treated empirically with ipecac it was necessary to resort to direct treatment, and in a few instances amebic cases previously scheduled for transfer to the United States, were able to return to duty with their organizations, instead, after a course of direct medication.

In August, 1908, while on transport, en route to the United States, I encountered an officer invalided home for amebic dysentery. He had been treated from the southern islands to Baguio over a period of months, and had submitted to an unsuccessful operation for producing an appendiceal opening through the abdominal wall for irrigation from above downwards. He had received the ipecac treatment upon several occasions, and he had also received colonic flushings, usually self-administered and without special attention to technique. He was emaciated, discouraged and disheartened, and looked forward to an early separation from the service. He was persuaded to take a course of high enemata with amebacide solutions, giving strict attention to technique to assure prolonged contact of the solution with diseased surfaces. These details include posture, adequate hydrostatic pressure, lengths of time of contact, adequate strength of solutions, and regularity. He arrived in San Francisco free from symptoms, fat, and fit for duty, and he is now performing duty in the United States. He expressed himself as being benefited as never before in treatment extending over nearly a year.

I do not claim that this man is cured, nor do I disregard the part which the sea voyage may have played in his restoration to health, but I do claim that his case exemplifies the superior efficacy of direct treatment in amebic dysentery. Unless we are willing to abandon our conception of the pathology of amebic dysentery we cannot escape the conclusion that direct treatment is the rational treatment.

Why should we treat a local condition of the colon by administering drugs by mouth, expecting a local action from them at the remote distance of twenty odd feet, any more than we should expect a local action upon the urethra, in inflammations of that structure, by mouth-administered drugs?

I do not undertake to say that ipecachuana is entirely without virtue in all cases of dysentery. Scheube states that when used in connection with calomel it is useful in catarrhal dysentery, but of little effect in gangrenous and chronic dysenteries, both of which latter cases come within the amebic or bacillary groups. Manson advocates ipecachuana in dysentery, as we are often reminded by its exponents, but he states also that it frequently fails, and that when found ineffective other drug treatment should be resorted to, mentioning the aperient sulphates, calomel and other drugs. He does not, however, disregard the local treatment of dysentery, but speaks with much praise of direct colonic treat-

ment. Manson, however, makes no distinction between varieties, in discussing the treatment, other than division into acute and chronic cases.

Concerning the treatment of bacillary dysentery I have nothing new to offer, but I believe that, internally, magnesium sulphate, intestinal antiseptics and opium, judiciously used, constitute the best drug treatment. However, I should regard topical treatment by enemata, with the strictest attention to the technique of their administration, confinement to bed with close dietary supervision and careful stimulation as the really important part of the treatment. It is to be regretted that treatment by antidysenteric serum has not, as yet, entirely justified its promises. Our efforts along this line should be continued.

Concerning the particular medicament for local use by enemata, I am less insistent upon a given solution than I am upon the principle of treatment involved. In amebic dysentery it should be the mildest efficient amebacide, and in bacillary dysentery it should be an effective antiseptic, as slightly irritant and toxic as may be.

I believe that there is more than one useful solution for both classes of dysentery. Strong reminds us that there are protozoal causes of dysentery other than entamebæ, and accepts the common intestinal parasites, including hookworms, as occasional causes of dysentery, as well as the rarer parasites such as *Balantidium coli* and *Schistosomum japonicum*. He also recognizes a dysentery due to malaria. During the past year a few cases of balantidium dysentery have been found in the Philippines, and I observed the first recorded case of infection with *Schistosomum mansoni* for the Philippine Islands in May, 1908, in an American. There is some probability that this case was imported from Porto Rico. Bilharzia dysentery was a feature of the case.

I would like to say something of leprosy, tuberculosis, malarial infections, filariasis and beriberi, all of them diseases of great medical and economic importance in the Philippine Islands, but I have already exceeded my allowance of time. I shall close, therefore, with a single word about the last-mentioned disease.

Beriberi, in particular, is a disease which just now, by reason of its continuance among the native troops, is giving special concern to the military authorities, both on account of the increased number of ineffective soldiers which it causes, and on account of the baffling front it has presented to investigators hitherto. To some of us who are especially interested in the disease it appears that the present local tendency or disposition to explain beriberi solely by dietary circumstances, on the hypothesis that it is a food toxemia, or that it is incidental to fat starvation, to nitrogen starvation, or, as has been recently proposed by an observer in the Philippines, to an excess of nitrogen or protein food, is quite without warrant.

This controversy has gone on for years, and many of the theories now being advanced have been discarded as exploded by the best authorities long since. Sir Patrick Manson states that the favorite view that beriberi is caused by special varieties of rice, or by diseased or mouldy rice, has been disposed of effectually by experiments upon a large scale, prolonged and scrupulously conducted. Most of the European students of this question are in accord with this belief and are inclined to look upon the disease as an infection. Manson, in the past, has leaned to the view that the germ is a saprophyte, not invading the human body but residing locally in the soil or the surroundings of man, and that its toxin is inhaled, swallowed or otherwise introduced into the body. The weight of opinion, however, and the weight of presumption from analogy, and especially from prophylactic experimentation, points to an organismal infection as the probable cause of the disease, be this infection one communicated directly from man to man or intermediately by living carrier or through infected food. One thing is certain, viz., that here in the Philippine Islands, with material at hand, we have not followed a single phase of the infection theory to a reliable conclusion, either positive or negative. Some who have had the best opportunities to observe the disease have been content to speculate upon it along lines previously followed by others to logical negative endings. There remains, then, this opportunity and this duty, and unless promptly embraced the honor of discovery and the credit for the resultant benefits to mankind will not go to Americans.

It seems to me that we should be more careful in making the diagnosis of beriberi. I am inclined to doubt whether all cases so reported are true beriberi, and I freely admit that I have been puzzled more than once by some cases much resembling rudimentary beriberi, yet lacking a convincing symptom complex and history. When it is possible to diagnose beriberi at all it shoud be possible to classify it, as both the classifications of Scheube, based upon clinical expressions, and of Wright, based upon pathological expression, are comprehensive and contain ample subdivisions. Owing to the native misuse of the term beriberi and to the difficulties in eliciting true and complete histories from our native patients we will frequently be handicapped.

It has been suggested to me by a careful observer that the Filipinos, while not a drunken people, are more given to tippling than is generally supposed. He points out the fact that almost every native or Chinese tienda (store) is also a saloon for the retail sale of liquor, and that many natives, both men and women, consume considerable quantities of gin and impure native alcoholic drinks, daily and habitually. I have confirmed this observation to my own satisfaction, and consider it not improbable that many of the indefinite cases reported as beriberi are in reality, cases of alcoholic neuritis.

MANILA, P. I.

SIMPSON AND CHLOROFORM.

BY VICTOR ROBINSON,

NEW YORK.

I also attended on two occasions the operating theatre in the hospital at Edinburgh, and saw two very bad operations, one on a child, but I rushed away before they were completed. Nor did I ever attend again, for hardly any inducement would have been strong enough to make me do so; this being long before the blessed days of chloroform. The two cases fairly haunted me for many a long year.—*Charles Darwin.*

A GOSSAMER mist glided out of cloudland, floating quietly and falling gently on the crags of the shore. The delicate water-dust struck the points, settled on the peaks, and broke into a vaprous fog. The opaque haze bedimmed the air, but the careful pilot in the sea below steered his passengers along the southern coast of the Firth of Forth. To the castled county of hilly Linlithgow were the tourists bound. Toward the green knolls that divide the lake in twain were they traveling. They were on their way to the remains of the finest ruin in Scotland—the Linlithgow Palace.

They walked around the fountain whose waters had once bubbled for the delight of royalty—now as dry as a rill that has ceased to be fed by rain. They looked at the chambers in which were born James II., James V., and Mary Stuart. They stood on the very spot where King Fieryface, from the window above, had hurled the lifeless body of the Earl of Douglas. They climbed the spiral staircase till they came to the bower where Queen Margaret used to wait for James IV.—who never returned from Flodden Field.

They lifted their eyes and saw the famous battle-field of Bannockburn. Here Robert Bruce defeated the English army, restored Scottish independence, and gave Robert Burns a chance to write what Carlyle called the mightiest war-ode in the world—*Scots wha hae wi' Wallace bled.*

Surely the scene is romantic enough, and many would fain dwell longer in the enchanted vicinity and imagine a chieftain fighting in every cave and cliff, while the minstrels chanted ballads o' the border. Some would sentimentalize on the kings and queens whose blue-blooded bones are mouldering like the walls of their favorite castle.

But no pen of mine can scratch a line of praise for monarch or warrior. Besides, lest it be imagined that every goose in Linlithgow is a swan, and all the lads and lassies be of blood-royal, I hasten to add that here lived, with his wife and family, a simple baker named Simpson.

Seven children tarried in the old home-nest, and grew lusty on their father's bread. They loved each other heartily, and made merry under the paternal roof. Yet one day they were warned to be very quiet. The baker himself walked on tiptoe, and spoke in whispers. A nurse moved noiselessly through the rooms.

Plaintive moans were heard. Such sounds were not strange to Simpson, and still they frightened him. He knew the woman he loved was fighting the brave battle and facing the great mystery. The cries increased—the pangs of childbirth are severe. Scream followed scream—the mother labored in the agony of agonies. A heartbreaking wail which the closed door could illy bar pierced every corner of the house and pierced likewise the soul of the father. Again that shriek escaped her, and the middle of the marrow of his bones seemed to shake. He rose in his nervousness, and shuddered with an uncommon fear.

He heard gasps. Was she struggling? Was she trying to breathe? Was she dying? Ah, what a shrill, keen outcry! How long must it last? Will it never end? Is there nothing to stop such suffering? Can the physician offer no remedy to assuage such violent anguish? No, Simpson, no. The doctor who now stands in your rooms is empty-handed, but listen—the times may change.

Open the door and peep in the chamber. On the bed lies your exhausted wife. The tears are in her eyes, and her face is pale with pain. But see what she holds in the crook of her elbow—a babe.

Father, you should tell the highlanders to play a gladder pibroch than their bagpipes yet have known; the times will change, the times will change. Tell them to pipe it over the tallest hills and across the faraway seas; the times will change, the times will change. Shout to them to blow stoutly on their sturdy reeds until the new tune brings a new joy upon the earth; the times will change, the times will change. A babe who is born of woman will bring unto woman a boon!

The Simpson family held a serious consultation—what was to be done with their youngest boy? It would be fine to send him to the University, but this required more bank-notes than Simpson received for his oaten cakes and barley bannocks. The sacks of flour were ready, the stone ovens were heated hot, and the yeast was added to the dough till the mixture rose like a living thing—but the cold money did not rise.

They discussed the matter again, and at night the father and mother whispered low and lovingly—so the children could not hear. The University idea became the dream and desire of their hearts—James must go.

Even if poor, there is little a united family cannot do. In union there is a strength that conquers adversity and puts a quietus on poverty. You cannot break the bundle of sticks when they are tied together. All the Simpsons agreed to save and struggle and sacrifice for the sake of the little brother, and thus it was that at the age of fourteen James Young Simpson became a student in the University of Edinburgh.

For the first two years he attended the arts classes, and then began his medical studies. The boyhood history of many men of eminence reveals the fact that they flunked in their quizzes at school, and received degrees only from the University of Life. But Simpson, being the son of poor parents, could not afford to indulge in this luxury. He seized the college curricula with both hands, and held on. He studied diligently, passed the required examinations, became a Doctor of Medicine at the age of twenty-one, and presented a thesis, *On Death from Inflammation*, which so impressed the Professor of Pathology that the recent graduate was offered and accepted an assistantship.

In this respect Simpson differed materially from a tall young fellow who entered the Edinburgh University the same year that he did. The aforesaid tall young fellow was the son and grandson of a physician, and he likewise commenced the pursuit of medicine. But he found the lectures so intolerably dull that it was impossible for him to prepare his lessons. Perhaps the cheerful fact that his father was well-to-do acted as an additional stimulant to his idleness. He soon deserted medicine in disgust, and solemly vowed never to look within the covers of a scientific book. Yet the day came when the Royal Medical Society of Edinburgh made him an honorary member, and the strict Universities of Breslau, Bonn and Leyden honored themselves by giving him an honorary M.D. This drone did not eat in the hive of inactivity till he was stung to death by the workers. The time came when he gathered more honey than all the others. He was Charles Darwin.

Who invented the telegraph? Morse, you say, but Morse built on Henry, who built on Steinheil, who built on Weber and Gaus, who built on Faraday, who built on Davy, who built on Nicholson and Carlisle, who built on Galvani and Volta, who built on Don Silva and Cavallo, who built on Lomond, who built on Lesage, who built on Stephen Gray, who built on others, back and still further back.

Who first scanned the heavens with a telescope? Galileo, you cry, but before the great Italian fitted a convex lens at one end of a leaden tube and a concave at the other, he had heard of an instrument which annihilates distance and magnifies small objects in a wondrous way. Some say—and with good reason—that the telescope was invented by

three clever Dutchmen, Jansen, Metius and Lippershey; others claim that long before these Dutchmen saw the light, Roger Bacon knew all about optic glasses and could combine them to form a telescope. And, reader, haven't you read that five centuries B.C. the Laughing Philosopher declared the Milky Way to be composed of vast multitudes of stars? Could he have seen this without some sort of a telescope? If so, then the eye of Democritus was as unusual as his brain.

Whom shall we call the Father of Anesthetics: Davy, Faraday, Pearson, Warren, Long, Jackson, Wood and Bache, Wells, Morton or Liston? That drugs have the power to cause deep sleep and insensibility was known to the ancients. The Shaksperean student will recall the master's frequent reference to the soporific effects of mandrake. Iago tells Othello of it, and Cleopatra calls for mandragora when Anthony is away, to sleep out the great gap of time. In the thirteenth century mandragora was extensively used as an anesthetic by Hugo de Lucca, and a full thousand years before this time Dr. Hoa-tho anesthetized his patients during surgical operations. Dioscorides and Pliny wrote of anesthetics, Herodotus mentioned hemp, and Homer sang of nepenthe.

So who deserves to be designated the Founder of Anesthetics? We do not know, but one event in the history of anesthesia is certain. In the distance the dust has settled, and from the scientific sky clearly shines this fact: the first physician to use an anesthetic in a case of childbirth was James Young Simpson. In this he had no precedent. He was inspired by the example of no one, unless, perchance, it were the murdered spirit of the Lady Eufame Macalyene, who in this very city of Edinburgh was burned at the stake by the ecclesiastics for using artificial means to deaden the pangs of labor.

The first drug which Simpson used in his obstetric case—January 19, 1847, a date worth remembering—was ether. Not being quite satisfied with its efficiency, he searched for an anesthetic of more energetic action. With his talented assistants, Drs. Keith and Matthews Duncan, he tested the properties of the vapor of iodoform, acetone, benzine, chloride of hydrocarbon, nitrate of oxide of ethyl, and various oils and gases. None of these caused him to cry, "Eureka!"

On the evening of November 4, 1847, the experimenters inhaled several substances without any marked effect. Ether still remained the unrivalled anesthetic. At this moment Simpson happened to remember that a Liverpool chemist named Waldie had spoken to him about a certain heavy colorless liquid. Simpson looked for the bottle, but could not find it. Probably when he was on the point of remarking that it wasn't of much importance anyhow, the amber-colored bottle was pulled out from the bottom of a heap of waste paper. Simpson scrutinized it again, and shook his head dubiously. It seemed to him too ponderous to be of much value.

But he took out the stopper, poured the contents in the tumblers, and the three inhalers eagerly shoved their noses to the brim. In a moment they rose—happier than when they had sat down. Dr. Keith's eyes grew bright and he laughed heartily. Dr. Duncan waltzed around the room, and Dr. Simpson, although he was usually the dignified Professor of Medicine and Midwifery at the University of Edinburgh, now wiggled his toes and would have stood on his learned head for a doughnut. Some ladies came into the room, and the gentlemen were remarkably amiable. They were more polite than Chesterfield, and the silvery stream of continual conversation which unceasingly flowed from their gifted tongues would have worried the mouth of Richard Brinsley Sheridan. The delighted ladies had never before met such pleasant companions. They did not know that these gay Lotharios were drunk—on chloroform! General Wolfe was killed at the moment of victory, and, unfortunately, in the midst of their newly-acquired popularity with admiring femininity, the secondary effects of the chloroform vapors became evident. The charming doctors became confused, and then like the crew in Coleridge's *Ancient Mariner*—a heavy thump, a lifeless lump, they dropped down one by one.

When Professor Simpson awoke, he found himself prostrate on the floor. His thought was as follows: "This is better than ether."

He soon prepared a paper on Anesthetics which he read before the Medico-Chirurgical Society of Edinburgh, and dwelt especially on the superiority of chloroform over ether. He began at once to use it in his obstetrical practice. One would naturally suppose that the whole world rose as one person and hailed Simpson as blessed, and that women especially felt like traveling from the ends of the earth to cast flowers in his path. Instead of this adulation, however, he was attacked on so many sides that like the lofty Milton he might have said:

". . . . . a barbarous noise environs me,
Of owls and cuckoos, asses, apes and dogs."

The controversy grew so bitter that had Simpson been a Semmelweis he might have become insane, and had he been a Horace Wells he would have hanged himself. But Simpson was the right man in the right place; he had the courage which defends and the courage which attacks. His was a warm and tender heart, but these desirable qualities did not prevent him from showing proper temper at unwarranted conservatism and unnecessary stupidity. He was no meek-cheeked weakling, and his hand was not lily-fingered. He was the leader of a great battle and he fought with a clenched fist, for the man behind the truth has little time to waste in mewing to the macrobiotic mush of the multitude.

Unfortunately, it was not only the unscientific rabble which shouted at Simpson. Meigs of Philadelphia, Ramsbotham of Great Britain, Scanzoni of Germany—men of brains and skill—opposed the innovation. Will it be out of place if I quote here the epigram with which I began my article on *Silence or Science?* "It seems to be an historical fact, governed by a natural law, that whenever a great radical steers his progressive ship over the waves of improvement, there is pitted against him a great reactionist, who by the weight of his authority beats back the advancing craft, and causes it to tremble and flounder among the sands and shoals of established usage."

It is interesting to recall the arguments which were urged against Simpson's introduction of anesthetics into obstetrics. Objections were seldom raised on the ground that the administration of chloroform would prove injurious to either mother or child. The disputants did not claim that the anesthetic would interfere with the natural progress of labor, or impede the uterine contractions, or that there would be an increased elimination of nitrogen in the new-born babe. Such statements—though in-

correct—would at least be entitled to the gravest and most careful consideration. But such arguments were not advanced. Instead, much stress was laid on the fact that an anesthetic sometimes arouses the amorous feelings, and that some women who have been under the influence of ether or chloroform have confessed that while anesthetized they believed they were engaged in the act of coition. That such occurrences were exceptional and unusual, while labor-pains were otherwise, was not taken into account, and it was both seriously asserted and solemnly maintained that if anesthetics were used in obstetrics the holy pangs of labor would be metamorphosed into exhibitions of sexual passion.

It was further argued that the maternal instinct was in danger of being abolished, as a mother could not love children whom she had brought into the world without suffering.

But even these were not the main contentions. Indeed, they were only breezes in relation to the whirlwind which was to overwhelm him; they were only the lapping of the waves in comparison with the howling storm which was to seethe about him. For, in endeavoring to assuage the pangs of childbirth, Simpson had forgotten to reckon with Genesis III, 16—the passage which contains God's malediction to mothers: "I will greatly multiply thy sorrow and thy conception; in sorrow thou shalt bring forth children."

The parsons got busy. Simpson was denounced as an impious meddler who sought to overthrow the divine decree of Providence. Of course, they called him an atheist, and his followers were considered imps of Beelzebub. Someone quoted Dr. Osborn's essay in which the author claims that God's curse as to painful parturition was intended to be continued as long as the world endures, which could be seen by the fact that the erect position of woman's body makes labor more tedious and difficult in her case than in the case of cows, sows and other quadrupeds which have the horizontal form.

But Scripture can be answered by Scripture, and Simpson on his part quoted Genesis II, 21, in which it is related that when the Lord wished to take a rib from Adam in order to make Eve, he "caused a deep sleep to fall upon Adam, and he slept." This citation helped to dispel prejudice in some quarters. It was seen that God himself made use of anesthetics in difficult operations!

Yet it is impossible to predict what would have been the immediate fate of anesthetics in general, and chloroform in particular, had not Simpson unexpectedly found an almighty ally, stronger than a fort of facts, more powerful than an arsenal of arguments. Darwin had a first-rate bulldog named Huxley which showed its teeth when its gentle master was attacked, but Simpson had a mastiff that disarmed criticism and made further abuse impossible. Queen Victoria was pregnant; there was a quickening within the royal womb; the day for labor arrived; Dr. Snow stood by her bedside; he put something on her face, and the regal mother inhaled chloroform. A few years later England's Queen conceived once more, and on the approach of parturition again availed herself of Simpson's anesthetic.

What had become of blasphemy? Where was sacrilege now? How about that passage in Genesis? Who now dare call anesthesia an invention of the devil? Did not God's right-hand favorite approve of it? Instead of a heretic Simpson became a hero; he was no longer a rebel, but a saviour.

Queen Victoria seemed grateful to the man who had eased her passage through life, for in due time the baker's son had a Sir in front of his name and a Bart. after.

The times had changed, the times had changed. The old order perished, and a better rose from its ashes. A blessing of inestimable value was conferred upon all mankind. He who was born of woman had brought unto woman a boon!

12 Mt. Morris Park W.

THE AFTER CARE OF THE INSANE.

By G. H. WILLIAMS, M.D.,

COLUMBUS, OHIO.

The object in bringing the subject of the after care of the insane to your notice is to show what has been accomplished along this line of work in other States and to cite the needs in our own. That such a work is needed in Ohio cannot be doubted, but so far practically nothing has been done.

The after care work was inaugurated with the object in view of assisting those in charge of State hospitals, by improving many existing conditions and coping with emergencies which constantly arise in the routine of such work.

Any new line of work undertaken by those connected with State offices or institutions is liable to close scrutiny as to its advisability or feasibility and as to the probable returns for the money invested. It has been proved that the After Care agents while engaged in following their line of work accomplished much good in various ways for the State hospitals. These different features I wish to outline more extensively.

The State Hospital for the Insane has for years past been the recipient of much undue criticism. In some instances it may have been well merited. There have been and always will be mistakes and at times mismanagement in this as in other lines of work, but even this does not warrant the exaggerated expressions of distrust so frequently heard in connection with the subject of the State's care of its unfortunates.

It has been found that the agents of the After Care Committee, in their frequent contact with expatients and friends of patients, by proper explanation and education, place the hospital in its proper and just light before the people of the community in which they visit.

This subject is of necessity of most interest to those concerned directly with the institution caring for those mentally aberrated. The crowded conditions of our present hospitals behooves us to adopt some measures to relieve the congestion and assist in the better care or treatment of those in our charge. Coupled with this is the fact that many cases of mental disease, either because of association with old companions, recourse to former habits, lack of self-attention, or kindred causes, recur, notwithstanding the fact that they left the hospital in good condition, both physically and mentally. Superintendents, knowing these facts, fear to discharge some cases even though they have recovered mentally.

In every hospital, excepting possibly those for the acute insane, there are many cases that remain in the institution merely for custodial care. Many of these cases could under the proper conditions be cared for outside.

At this time I wish to cite and state briefly some facts in regard to ten male patients who would be-

yond doubt be suitable cases for after care work. They are selected at random from our records at the Columbus State Hospital; the cases having been residents all of or part of the time from April 1, 1907, to April 1, 1909.

Of the ten, three are dementia præcox cases, two are manic depressive, one an imbecile, and four are alcoholics.

Case I, has spent, since April 1, 1907, 273 days inside and 458 outside the hospital, going in and out on several trial visits. His home surroundings are not pleasant or agreeable and not in the least conducive to his well-being. His mother does not exercise proper judgment in her care of him. The boy usually returns to the hospital of his own accord and is at once placed at some light employment and allowed to go about the grounds unattended. He is never quarrelsome while in the hospital and is withal a case who could without doubt spend much more of his time outside if the proper environment was created for him.

Case II.—This patient has spent 220 days in, and 511 days outside. He is a young man who was admitted in a more or less maniacal state and for several months was regarded with anything but a hopeful prognosis. He had a short time previous to his commitment been deeply engrossed in school work, and expected, upon his discharge, even against the advice of the physician to again engage in the same line of work. This patient should have had some one to advise him in regard to the kind of occupation best suited to the retention of his good mental condition.

Case III has spent all of the past two years in the hospital. During the past five years he has made at least two attempts to find some employment in the city. He has succeeded, but when he attempts to assume the necessary responsibility incident to his independent existence, he cannot stand the strain and returns to the shelter of the hospital. He is a young man of good habits, and, under proper home environments, would no doubt lead a very happy life.

Case IV is a case of manic depressive insanity. He has been in and out of the hospital for at least six different trial visits since his first commitment, December 1, 1902. Since April 1, 1907, he has spent 351 days inside, and 380 days outside, the time being almost equally divided. He is a farmer who owns quite a large farm, with always an abundant amount of work on hand. He is rearing a family, and always does much more work than is proper. As a rule he returns to the hospital in a more or less disturbed condition, reduced physically, bowels constipated, etc. He has so far refused to come to the hospital for advice while on trial visits, and is a case that would profit abundantly by having some agent call on him with timely advice as to the proper care of himself.

Case V is another maniacal case, who has been in the hospital under two distinct commitments. The last period he was in the hospital but 67 days. His occupation is that of a blacksmith, and during the busy seasons the patient works both day and night, neglects his physical welfare, develops insomnia and delusions, becomes maniacal, and returns to the hospital. This is a case in which advice is very necessary.

Case VI is one of imbecilic basis. By occupation the patient is a blacksmith. He has made several trips to the hospital, staying for greater or less periods of time. During the past two years he has spent 292 days in the hospital. As soon as he recovers from the excited condition in which he generally returns, he is placed at work, and under proper medical supervision gets along very well. When at home, owing to poor home surroundings, and the need of a dependent family, he is of necessity compelled to work much more strenuously than he should.

Cases VII, VIII, IX, and X are selected from the different classes of alcoholics in the hospital. They have been patients since 1902, 1891, 1893, and 1903, respectively. All of them have spent the last two years continuously in this institution. These are cases of at least the average mentality, some more than the average. Some have held important and responsible positions. Two of them have no homes but the hospital, and are hardly of sufficient judgment and will power to make a separate livelihood, but under proper home surroundings would live comfortably for the remainder of their lives.

To summarize: We have ten cases of different kinds who have during the past two years spent collectively 4,858 days in the institution. How many of these days could they have spent outside had there been suitable surroundings, proper companions, and someone to advise them, and to look after their personal welfare? Estimates are only matters of conjecture. After surveying the cases and studying them with their many characteristics, it seems both fair and reasonable to suppose that one-fourth of the total time could have been saved to these unfortunates. Granting such to be the case, it means a total of 1,214 days. The average daily per capita cost of keeping each patient during the years 1907-1908 was approximately 48 cents, so that the cost of keeping our ten patients the 1,214 days was $582.72. We all realize how fallacious figures are at times, but we have cited the above amounts merely to show that the subject of after care is a vital one if it is judged from a pecuniary basis alone. It certainly is not economy in any sense of the word to keep within a hospital patients who are in no further need of treatment, and who cannot be cared for as cheaply there as they can be outside. To view the subject from the humanitarian standpoint, the basis from which it should be judged, we have no right to allow such conditions.

During the past year the total cost of the entire after care work in New York was $1,700. For next year they asked $2,500. If one institution with ten cases alone could have been benefited nearly $600, does it not seem to be purely a business matter to make some efforts to remedy such defects? The State is certainly not justified in keeping under restraint, in no matter how modern or well equipped the hospital may be, chronic and harmless patients who can be more cheaply, more comfortably, and as, or even more, safely cared for under outside influences. The State has certainly been negligent in this one respect. One of the first objections to the work is to find places of employment either for those who have recovered or for those who are of the harmless chronic classes. Several different lines of work have been proposed for such persons. In some localities the experiment of placing insane patients in farm dwellings has proved of marked benefit from the medical, as well as from the financial, standpoint. The patients are exceedingly well pleased to return to home life, and take far more pleasure in such living than they do in the dances, entertainments, etc., of the usual hospital routine.

The objection of the commonwealth, that homicide, suicide, or some other casualty would take place, is far from being proved. So far, as a rule, these accidents are far less common in the free, out-of-door life than they are in the places of restraint. For over forty years Scotland has had her dependent insane in private dwellings, and now boards out at least 23 per cent. of this class. In some cases it has been found feasible to have old attendants or nurses who have left the hospital take patients into their homes at a very nominal cost. These persons more readily understand the mentally sick, and can do more to assist them to a rapid recovery.

Some institutions allow their patients who have recovered and have no home to become employees at a greater or less salary. They make their homes in the hospital under the conditions best suited to them until such opportunities as they desire arise, and they are able to go out into the world, shouldering the necessary responsibilities of their existence in the struggle with their fellow creatures. Any mental patient that is cured should be regarded in the same light as the normal individual, and should have sufficient work of a kind adapted to each individual case.

As New York and Massachusetts have taken perhaps more interest in this work than the other States I wish to state briefly what they have done. The care of insane in private families was first inaugurated in Europe about 1850, and in Massachusetts between the years 1880-1885. John E. Fish states that during 1907 there were 267 patients, 13 men, 254 women, living with families outside of State hospitals. They were living with unquestionable advantage to themselves, and without injurious influences upon others.

The work has been carried on actively in New York during the past three or four years. At the present time they have various committees and sub-committees who look after the patients discharged from the different hospitals. The officers of the hospitals work in conjunction with these committees and assist them as much as possible. A short time before the patient is to leave the hospital the fact is reported to the agent, who investigates the home life, the surroundings into which he is about to enter, and whether or not suitable employment is at hand. Many times the statement that a patient is discharged to the care of his family means but little, as the home surroundings are very poor, and in every way deleterious to his continued good health. His dismissal under such conditions means a far greater hardship than remaining in the hospital.

The After Care Committees look into such conditions, and try to remedy them so that relapses and returns to the hospital may be prevented. After the patient has left the hospital the agent makes periodical calls on him, inquires into his welfare, gives suggestions, and if necessary, has him report to the hospital for advice and treatment. The patient and patient's friends in practically every case feel very kindly toward the agent. They know that someone is interested in them, and as a rule the agent is kindly received into the home. Conditions are freely discussed, and evils remedied. The agent is able many times to relieve any feeling of uneasiness about the patient's treatment while in the hospital, and to assist in effacing the prejudice that exists in the minds of the laity in regard to such institutions.

The small hospitals with their few patients can quite easily come in touch with the home life of the individual case, and find out wherein some of the causative factors of the patient's mental condition may lie, but with the large hospital such is not the case. So much the more need of some investigating officer or agent. The patient that is ready to be discharged needs advice as to his future, as to his home life, the company he expects to keep, and the work he expects to follow. The physician can give such advice, but there is need of someone to see that his advice is followed. For at least two reasons it has been found advisable and more profitable to employ agents who were not in any way connected with the hospitals. First, the patient's friends feel more freedom in discussing the patient's welfare with such persons, and secondly, in the usual hospital none of those fitted to do such work have the time to devote to it.

The time was, and not many years since, when the unfortunate who in many cases through no fault of his own, was afflicted with some mental disease, was considered as the leper, one to be shunned, a hopeless wreck, a derelict of society. He in many cases could not find a haven with his family doctor, for even he was only too glad to shift the care and responsibility incident to the welfare of the "crazy man" to the shoulders of some other individual. But the dawn has certainly broken for the insane. With the present modern facilities the percentage of recoveries in the usual hospital excepting those for chronic or epileptic insane, ranges from 20 to 30 per cent. of the cases admitted. There can be no doubt that our methods now in use will, to those of the next generation, seem crude indeed, but the constant aim of the alienist is to use every means that comes under his control to further the work of caring for his brother in distress.

The after care agent gives him another avenue of help. With this means of assistance the percentage of recoveries can be increased, and the work begun for the individual while in the hospital can be carried on outside until the patient is once more the useful member of society that he was before his disease developed.

It is hard at times to overcome the prejudice of employers, some of whom will not employ under any circumstances a person whom they have known to be insane. Many will receive them on certain conditions, while some are broad minded and optimistic enough to assist such people to their former stations in life. There are numerous insane persons neither destructive or dangerous, who were cared for at home many years. While at home they are neither feared nor shunned by their friends or neighbors; but as soon as they are committed to a hospital for the insane the token of disgrace is placed upon them too often to remain for life. Mental patients realize these handicaps and many of them prefer to remain in the hospitals rather than to go out and labor against such odds. Many relapse on account of trivial things connected with their work, incidents which could have easily been adjusted by some one who has an insight into their past and present existence.

In perhaps no special class of cases is the after care work needed more than in the alcoholics. The constantly increasing numbers that are being sent to our hospitals as a rule for short periods only is appalling. As one sees such cases admitted, in a few weeks improve or for the time recover, leave the hospital, and within a few days become intoxicated

by associating with their old companions, he certainly has a very narrow mind who cannot see the need of some one to assist such patients.

If we are to conserve the beneficial results of hospital care to treat the patient justly and wisely, with full knowledge of his past existence and due regard to his future welfare, not as though he were an outcast, an isolated unit, but recognizing his duties to his family and other members of society, we must make some provision for after care for those who may need it.

TONSIL REMOVAL, OPSONIC INDEX, AND IMMUNITY.

By BRYAN D. SHEEDY, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF LARYNGOLOGY, FORDHAM UNIVERSITY MEDICAL COLLEGE; INSTRUCTOR IN DISEASES OF THE NOSE AND THROAT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The subject of immunity to disease and the factors that bring about that condition are interesting to all physicians alike, whether working along special lines or devoted to the broader field of general medicine.

Since Sir Almroth Wright made his rather absolute statements relative to the opsonic index and general immunity, and the relation that tonsillar tissue probably bears to the subject of immunity, medical men in all parts of the world of all kinds and classes have been discussing the subject with much vigor.

It was not long after Wright's paper was published, however, before laboratory specialists and investigators began to improve on his teachings, and so rapidly did changes occur that few physicians, with the limited time at their disposal for such work, could keep pace with the strides and alterations made in his teachings, and if you ask almost any one to-day to explain what he means by immunity, the opsonic index, and other matters bearing on immunity, and the relation the tonsils probably bear to it, he will at once become indefinite and ambiguous in his statements. This is not surprising, for daily do we read of new teachings, some of which though not directly opposed to Wright's views are far from agreeing with them.

I am free to confess that for a number of years, as a teacher of medicine, my ideas as to the real function of tonsillar tissue have been quite as hazy as the teachings imparted to me many years ago by my good professor, who stated that he really could not tell us or give us any good reason why we had tonsils.

Many of us hoped that when Wright's paper was published we had at last reached a stage in our development where we could point to something positively definite as to the real function of the tonsils and the relation of that function to immunity.

In studying the subject carefully, we find that all tonsillar tissue is derived from the hypoblast and the special ring of lymphoid tissue found in the oropharynx, forming the faucial tonsils, pharyngeal tonsil, and lingual tonsils, is really the surplus portion of that membrane left over where it joins the membrane of the anterior portion of the nose, the epiblast.

The hypoblastic membrane extends from the oropharynx above to the anal opening below. In early fetal life this membrane is filled with lymphoid structures of a uniform thickness and consistency, but as the fetus grows certain portions of this membrane become absorbed while certain other portions develop and go to make up the glandular structures that in the oropharynx we call tonsils, in the stomach gastric follicles, in the intestine, duodenal glands, and in the lower portion of the small intestine, Peyer's patches. The vermiform appendix is lined with this same lymphoid structure, and the mucoid glands of the rectum, so often swollen and enlarged and projecting as hemorrhoids, are often nothing more than enlarged rectal tonsils.

In the embryo the faucial tonsil is not developed until the fourth or fifth month, so that when we are considering its function we must keep in mind that the prior development of the embryo did not depend upon any tonsillar function.

At birth we find the tonsils fully developed and performing their functions. We further note that when the tonsils are enucleated after three years of age the child apparently suffers no loss; the tonsils, like adenoids, decrease in size from the third or fourth year up to puberty if the patient has been healthy and free from attacks of tonsillitis up to that age.

If we study the faucial tonsils more particularly we find them made up of lymphoid tissue arranged in a very special manner. We find the surface of the mass studded with depressions leading into small pouches or pockets, frequently called crypts or lacunæ, each lined with stratified squamous epithelium. Into the bottom of these crypts or pockets we find mucous glands depositing their secretions. Beyond and surrounding this glandular tissue we find more or less fibrous tissue, making up what is generally called the capsule of the tonsil, and beyond this the loose connective tissue on which the tonsil rests.

In considering the functions of the tonsil and the part it plays in early immunization we must take into consideration and study carefully the teachings of Goodal, Wood, Wright, and others, all practically agreeing (1) that the tonsils possess phagocytic properties; (2) that the lymph currents from the mouth and nose converge toward the tonsil; (3) that the lymph passes into the cervical lymphatics through the tonsils.

Some observers have noted that foreign particles pass with the lymph current through the epithelium lining the crypts of the tonsil, but that living bacteria remain in the crypts.

When we consider the location of the tonsils above described, generally spoken of as Waldeyer's ring, we are forced to the conclusion that this circular fortification of secreting tissue was not erected there without some good purpose in view. This becomes more apparent when we stop to consider that, while all roads at one time led to Rome, all channels, whether over or under the mucous membrane, lead toward the tonsil. Food laden with bacteria on its way to the stomach is forced against some portion of the tonsillar ring by the muscles of deglutition. Food ejected from the stomach is also forced against it and the millions of bacteria passing into or out of the body through the nose and

mouth pass or come in contact with this fortification.

One investigator pointed out that bacteria entering the crypts of the tonsil remained there while their toxins passed on into the blood current *via* the lymph channels, and those toxins in the tissues or by their presence in the circulation stimulated the opsonins or resisting substances, thus developing what we call immunity.

By immunity we mean that condition which prevents the gaining of a foothold by germs or bacteria in the living body, or that condition which overcomes or neutralizes their harmful products or destroys the organisms themselves.

Not all animals (including man), however, suffer from an infection after the germs of a given disease have been introduced into the system. For example, we may point out the goat and tuberculosis, the white rat and anthrax, the chicken and tetanus; yet all of these exceptions may conform to the rule when subjected to certain unusual conditions. According to most of the writers of the present time—and I may say that for this article I have accepted many of the points as well as definitions from Good's article on early immunization—according to that article immunity is divided into (1) naturally acquired immunity, and (2) artificially acquired immunity. By naturally acquired immunity we mean that immunity which is established by the natural forces of the body. This is brought about by different organisms existing in the body of the individual throwing off their products into the circulation. As an example we need but mention measles, diphtheria, tonsillitis, etc.

By artificially acquired immunity we mean that condition of the system which is brought about by inoculating the patient with live germs which ordinarily cause the disease, or by injecting into the body of the patient the products of those germs. Any material used to induce this immunity, either by injection or inoculation, is generally known by the term vaccine. As a definition for this term we may say that it is any substance derived from bacteria which when taken into the body fluids is capable of exciting or developing protective substances.

Protective substances are certain anti-substances found in the fluids of the body which antagonize disease germs. These anti-substances act in several ways—principally by mechanical interference and physiological action. As an example of the mechanical interference we may mention phagocytosis and opsonic power of these anti-substances, and as an example of the physiological process we would mention agglutination and bacteriolysis.

By agglutination we mean that process whereby bacteria are rounded into clumps; an example of which is seen in typhoid fever.

Bacteriolysis is the physiological destruction of the bacteria by the anti-structures.

Opsonic power is the ability the body possesses of preparing pathogenic bacteria to be acted upon by the phagocytes.

Phagocytosis consists in the destruction of the bacteria by the phagocyte after the bacteria have been prepared by the opsonins.

A phagocyte is any cell which has the power to take within itself a foreign substance and destroy it. This process may be carried out in the form of a digestion, or the phagocyte may so entwine itself with the bacteria that both are inseparable and as they pass into the excretory ducts are destroyed.

Opsonins are substances distributed through the fluids of the body produced as a result of the tissues resisting bacterial irritation.

Artificially acquired immunity may be established in two ways: (1) By injecting bacteria or their products into an individual whose tissues will react and produce protective substances or antibodies. These protective substances aid the body by neutralizing the bacterial toxins or by destroying the bacteria themselves. These protective bodies may remain in the system for years, thus causing a temporary or permanent immunity, as the case may be. When immunity is secured in this manner it is termed active immunity.

(2) If the serum of an actively immunized animal is injected into a second animal the second animal becomes immune without its cells developing the anti-substances. This process is termed passive immunity. If the serum used in bringing about this immunity contains only the property of neutralizing this toxic product of the bacteria, it is known as antitoxic immunity. It should be noted that bacteria against which antitoxic immunity is established give off their poisons while alive. An example of this variety is the antitoxic serum used in diphtheria. It is also observed that some bacteria give off a toxin after their death. Any serum introduced for the destruction of organisms is known as antimicrobic serum. In all cases where this serum is employed the patient shows marked reaction or a toxemia from its use.

All immunities except inherent immunities may be produced by the processes in the tonsil. Natural immunity is brought about by inflammation in the tonsil, and a species of artificially acquired immunity is produced in the crypts of the tonsil by agglutination and the development of opsonic power.

That children of tender years are not thoroughly immunized is proven by the fact that they so readily succumb to the many germs attacking and destroying child life, thus, for example, of pneumonia, diphtheria, scarlet fever, etc. I interpret the opinion of investigators to-day to be that the normal tonsils are most active during the first two or three years of life, and that they are not absolutely necessary to the wellbeing of the individual after the period of childhood. The fact that they are not necessary is proven every day through our enucleating them without apparent injury.

It is believed that the ring of lymphoid tissues surrounding the oropharynx, as well as the other masses of lymphoid tissue throughout the intestinal tract, have the same functions, but to a lesser extent, than we find in the faucial tonsils.

We therefore conclude that the tonsils in young children serve an important purpose and should not be removed unless they are so far diseased as to have their normal functions interfered with, when, instead of acting as a fortification and protection against the inroads of bacteria, they may, and very often do, become the portals by which the enemies to health gain admittance.

164 West Seventy-third Street.

Pathogenesis of Unilateral Pleuritic Effusion in Cardiac Disease.—Feliziani says the pathogenic factors in this condition are pericarditis, perihepatitis from hepatic congestion, and pulmonary infarctions. Pulmonary hemorrhagic infarctions are the cause in the great majority of cases. These arise from cardiac diseases, especially of the atrioventricular orifices, small coagula being detached and carried into the lungs to form pulmonary embolisms. Aortic affections and arteriosclerosis also cause embolisms. The upper level of the fluid is not above the angle of the scapula.—*Il Policlinico.*

A NEW TEST FOR BLOOD.

TESTING for the presence of blood under various conditions is a common procedure in both clinical and legal medicine. For this purpose there are several good and reliable methods which give accurate and delicate indications of the presence of the blood pigments. Most of these are, however, more or less complicated or require a certain amount of expensive apparatus, and are, in consequence, though of value in the laboratory, somewhat cumbersome for private practice. The test requires a microscope and the spectroscopic test demands an instrument but rarely found in the equipment of the practising physician. The guaiac test is good, and is made in a test tube, but has the disadvantage of requiring drugs not often found in an office, and demanding careful technique in carrying out its various steps. Recently, however, Julius von Kóssa of Budapest has devised a new blood test (*Deutsche medizinische Wochenschrift*, August 26, 1909) which is simple and requires only such chemicals as are found in the cabinet of every country physician.

The principle of this test is based upon the insolubility of hemoglobins in alcohol. To ten cubic centimeters of a watery solution of the material to be tested is added an equal amount of ninety per cent. alcohol. The solutions are mixed carefully without shaking and five cubic centimeters of chloroform added. This is then mixed gently. If blood is present the hemoglobin is precipitated out of the solution, and falls to the top of the chloroform, where it collects in a layer of tiny red droplets. The author claims that the test is extremely delicate, giving a definite reaction with a solution containing so little blood that a layer six centimeters thick gives no absorption band visible in the spectroscope. In applying the test to the urine, von Kóssa varies the concentration in that to the ten cubic centimeters of urine he adds an equal amount of distilled water and only five cubic centimeters of alcohol. After adding the chloroform, as above, especial care must be taken to prevent shaking and consequent emulsification. Occasionally instead of the hemoglobin droplets a rose-colored ring appears between the chloroform and the alcoholic solution. If this happens the overlying fluid is poured off and a few cubic centimeters of alcohol added, whereon the typical droplets appear.

The simplicity of this test is an advantage, and if on further use it is found to be as delicate and as accurate as the author considers it, it should prove, though perhaps not a great addition to a scientific laboratory, at least a useful help to the practising physician.

ALCOHOLISM, CRIME AND INSANITY.

AT the annual meeting of the Medico-Psychological Association, held on July 22 and 23 last at Leeds, Mr. L. O. Fuller read a very interesting paper dealing with the above subject. He regarded postnatal environment as a very potent cause of degeneracy. The child is naturally imitative, and although he may not be intellectual he will copy the habits of his parents with great facility, and seeing that in many cases parents drink and frequently suffer from tubercle and syphilis, it is not surprising that their offispring contract their vices and become themselves degenerates and breed degenerates. Mr. Fuller is of the opinion that the most scientific way of dealing with degeneracy is one which aims at removing the causes rather than alleviating the symptoms, a great desideratum being much greater elasticity in the educational system. The inebriate should have a period of instructional detention, with a view to prevent drink habits being firmly formed; this should combine medical instruction with disciplinary methods. He strongly objected to a predetermined sentence which to the youngster was often a hardening process; it threw him into the ranks of the unemployed and often the unemployable, and finally he became hostile to society. Mr. Fuller advocated the establishment of receiving houses to which first commitments for inebriety could be made.

The general custom in England as regards the treatment of inebriates appears to be their detention in a reformatory for a period of three years, and it was against this fixed term that the majority of speakers at the meeting referred to protested, for it is absurd that all cases sentenced to reformatory treatment should be subjected to detention for a period of three years neither more nor less. In many instances, after three years of such life, a man is good for nothing upon his release. He has forgotten how to work.

The problem of how to deal with vice in the great cities and especially how to treat the inebriate is most pressing. The modern methods of living, especially in towns, leads directly to degeneracy, for in the crowded centers of population habits of drink and immorality are fostered and predispose to crime and insanity. It is impossible wholly to remove the causes, although undoubtedly the most strenuous efforts should be made in this direction. There must, however, be numerous cases which call for treatment, and it is in the best interests of the population at large that this treatment be rational and effective as possible. It must be borne in mind that the children of degenerates will be probably worse than their parents, and therefore if the race is to survive and prosper, it behooves the sensible healthy inhabitants of a country to use their utmost endeavors to stamp out vice and intemperance.

VENTILATION IN THE TROPICS.

A WHITE person who goes to a tropical country to live for any length of time, if he wishes to keep in good health, must follow certain definite rules. One of the most fruitful causes of the deterioration of health of Europeans in the tropics is held to be the defective ventilation of the dwellings and other buildings. This subject has certainly not received the notice its importance deserves.

A correspondent of the *Lancet* sends to that journal, August 14, a very interesting communication dealing with the question somewhat fully. A tropical atmosphere is not only of a high temperature but is charged with moisture in varying degrees. The more moisture there is in the air, the greater the injurious effect, as a rule, on the human being. If energetic steps be not taken to ventilate the dwellings, it stands to reason that in such circumstances the air must be inimical to health, and, of course, must especially adversely affect the white people not born in the country. The writer in the *Lancet* points out that the ventilation of dwellings in the tropics presents features that are totally distinct from those of cold or temperate climates; "this," he says, "is proved by the failure of appliances, successful in Europe, that are brought out from time to time to be attached to buildings in hot countries." Such inventions depend for their efficiency almost entirely on the movement of the wind. In India, the country concerning which the writer discourses, although his remarks apply to a greater or less extent to the majority of tropical lands away from the seacoast, the period of greatest heat is usually accompanied by a dead calm, which affords no assistance to the ventilation. In fact, the methods of ventilation in vogue in northern countries generally are comparatively useless in the tropics, but with the usual obstinacy and adherence to customs of the white man, he is slow to adapt himself to the exigences of climate, and is apt to think, until he learns the lesson from harsh experience, that as regards ventilation, the means that are suitable to temperate lands are fitting also for tropical countries. When there is no wind, it is obvious that a ventilation which relies upon a current of air for its efficiency is of no avail, and therefore other methods of ventilation must be sought.

Houses in tropical countries are, as a rule, kept closed, in order to exclude the burning rays of the sun, but unless ventilation is good, this renders the inside air impure and unwholesome, for the reason that perspiration is much more profuse in hot climates, thus necessarily tainting the atmosphere. The writer in the *Lancet* runs over several modes of ventilation which came under his observation when living in India which there is no space to discuss here. It is pointed out, however, that in hot weather the difference of temperature of the air indoors and out is comparatively small, and as that difference is all there is in the absence of wind to produce a current, vertical openings alone are effective in India, that is to say in most tropical lands.

So far as personal ventilation is concerned, clothing is a factor of much moment. A European in the tropics, when indoors, wears more clothing than he really needs, for the greater the amount of clothing the greater the velocity of current required to carry off the surplus heat, and this strength of current is liable to cool the head too quickly and cause catarrh. Electricity should greatly simplify ventilation, for by the aid of electric currents it should be neither difficult nor unduly expensive to renew and cool the air supply to suit the requirements of the season and the occupants. But in India, so far, the only use made of the electric current has been the substitution of an overhead fan for an overhead punkha, neither of which renews the air supply.

THE DANGERS OF SUN BATHS.

THE readers of the daily newspapers who read and believe everything published pertaining to medicine must look upon the average German physician as a sort of a high grade bathhouse attendant. For it is at about this time of the year that the annual homecoming of American millionaires occurs, that throng of humanity with "livers" and with "rheumatism" returning from the renowned and always fashionable German health resorts, rearmed for the social gaiety and dissipations of the coming winter. Some of these have consulted eminent physicians and surgeons of Berlin or Vienna, but of that one does not hear. What the papers tell and what the layman remembers is that they took baths. These may have been mud baths, salt baths, sulphur baths, dust baths, sand baths, hot baths, air baths, whey baths, sun baths, Schott baths, or, if the patient's pocketbook is sufficiently well lined, even champagne baths. The special variety is immaterial, the point of importance being that the patient went to Europe and took baths. Against the excessive employment of one of these forms of nature cure Grawitz utters a warning in the *Deutsche medizinische Wochenschrift* for August 19, 1909, in which he says that the sun bath may be not only not a source of health but an actual menace to the patient. The author has noted in many persons who had exposed their naked bodies to the rays of the sun for several hours in various Berlin sun-bath parlors symptoms often serious and at times dangerous. Besides dermatitides, he has noticed irregularity and acceleration of the heart, systolic murmurs at various orifices, increased cardiac dullness, especially toward the right, high pulse tension, accentuated second sound, and in a few cases collapse from cardiac insufficiency. The temperature was elevated in some cases and headache and general malaise often lasted for days. The evil effects of undue exposure to the rays of the sun have of course been shown before, notably by Woodruff in his work on "The Effects of Tropical Light on White Men," but the impulse to sun worship has been through centuries so firmly planted in mankind that it is well to repeat from time to time such warnings as that of Grawitz.

VACATIONS.

THIS pleasant topic conveys fresh recollections of pleasure at the summer's close—of days in cool valleys, hours upon the water, and meeting with interesting people. The physician has sent away many to such enjoyment, and himself probably

found an interval to test these relaxations. Most of us approve of vacations. Yet the question is still asked, Are vacations necessary? Do they benefit? Should our lives be lived in such an unhygienic fashion that we have to drop everything and seek refreshment, health, life itself, in an utter nullification of all that life had meant for us? A strange ordering of life, that, if it is self-destructive! There are many reasons for patients being sent away. Some expect this, and relish the order of the medical man, believing it gives importance to them and their illnesses. Other patients are stupid. They will not be reasonable in work. We must tear them from their fatal paths, and can do so only by forcing them to depart from localities and atmospheres which seem to act like whips to tired horses. Separating these groups, however, there remains the great mass of humanity which does not take vacations, at least not voluntarily, and cannot think of life aside from labor. Happy as the thought is, the notion of a break in life is not always feasible. The late Russell Sage is said to have held that vacations were unnecesary in the widest sense, and that life should be so ordered, that routine could relax, and that in the natural course of events a variation in routine, of a broad character, would be attainable. It is a fortunate man, or woman, who can find relief even in routine. Meanwhile, we have no objections to vacations, none at all! We are sorry we need them—and glad to take them.

Ataxia Following Diphtheria.

The occurrence of the common form of flaccid paralysis following diphtheria, appearing as it does, either in the palate, the ocular muscles, or as a monoplegia, diplegia, or hemiplegia, is such a frequent complication of the disease, that it is apt to overshadow in one's mind a different type of postdiphtheritic nervous disease which, if not appreciated, occasionally leads to grave errors in diagnosis, and more especially in prognosis. This is the postdiphtheritic ataxia, a condition which appears suddenly following an acute attack of diphtheria and may at first, and even after careful study, be extremely difficult to differentiate from true tabes dorsalis, the definite diagnosis being at times possible only when, at the end of from one to six months, the patient makes a complete recovery. These cases, though rare and scarcely mentioned in the text-books, should always be taken into consideration in determining the diagnosis and especially the prognosis of cases of ataxia with sudden onset. Still another type of postdiphtheritic ataxia, possibly even more rare than the last, is illustrate l by a case reported by Brückner in the *Berliner klinische Wochenschrift* for August 23, 1909. The patient, a little girl of four, during the second week of laryngeal diphtheria suddenly developed inability to speak and at the same time a high grade of ataxia, without paralysis or altered sensibility. The intelligence was affected, and on the return of the power of speech the phrasing was of a delayed, monotonous, expressionless, and at times explosive type. Later paralysis of the bladder and the sphincter ani developed. The disease lasted for several months and then gradually improved, ending finally in complete recovery. The case here reported Brückner considers to belong to the type of acute cerebral ataxia, and he holds very justly that its occurrence following diphtheria is a distinct rarity.

News of the Week.

Hospitals for the Hudson-Fulton Celebration. The following location of floating and field hospitals has been announced for the Hudson-Fulton celebration:

Floating Hospitals.—St. John's Guild hospital ship *Helen C. Juilliard* (police), Ninety-seventh Street, Hudson River. Barge *Starin*, Spuyten Duyvil Creek—life-saving station, 24 beds.

Field Hospitals.—Dyckman Street, Hudson River, 4 beds. Fort Washington, 178th Street, 4 beds. 129th Street, Hudson River (1 ambulance), 4 beds. 111th Street, Hudson River (2 ambulances), 16 beds. At Bluff, Recreation Park, 108th Street, Hudson River, 6 beds. Float, Hudson River Yacht Club, 107th Street, Hudson River, Telephone 2355 Riverside. 50th Street, North River, necessary cots. 42d Street, North River (1 ambulance). Telephone 3940 Bryant. 34th Street, North River, 4 beds. Small park, West 23d Street, east of ferry, 8 beds. 15th Street, North River. Pier 20, North River, Chambers Street. Battery, opposite Pier A, 16 beds. Brooklyn end of Brooklyn Bridge. Municipal Ferry, St. George, S. I.

Hospital Signals.—By Day—White bunting flag, with gold cross, and white bunting flag, with green cross. By Night—Will be a balloon flying from flagpole of hospitals, with green and white lights.

Plague Epidemic at Caracas.—According to dispatches recently received at the State Department no new cases of bubonic plague had been reported in Caracas for eighteen days, which fact is taken to mean that the epidemic is over.

Poliomyelitis in Minnesota.—The epidemic of infantile paralysis has been so severe in St. Paul that the schools have remained closed in consequence. The disease is reported also to be prevalent in Minneapolis.

Cholera in St. Petersburg.—Dispatches from St. Petersburg state that during the fifteen months of the cholera epidemic there have been 14,865 persons ill, and 5,759 deaths. The cases are confined largely to the illiterate classes.

A Journal for the Study of the Circulation.—We have received the first number of a new journal, entitled *Heart*, established to record the new facts and new conclusions relating to hemodynamics. By means of new instruments and new methods of approach, the study of disease of the heart, especially of the heart muscle and its several parts, has of late been prosecuted with zeal, and it is believed by the projectors that the knowledge acquired by such investigation is of sufficient importance to be collected and recorded in a special journal. The editor of the journal is Dr. Thomas Lewis, assisted by Drs. Gaskell, Cushing and Mackenzie of London, Hewlett of Ann Arbor, and Stewart of Cleveland, with a large staff of collaborators in Great Britain and this country. It will be published quarterly by Shaw & Sons, London. The first issue contains papers on nodal bradycardia by James Mackenzie, paroxysmal tachycardia by Thomas Lewis, irregularities of the mammalian heart observed under aconotine and on electrical stimulation by A. R. Cushing, and the measurement of systolic blood pressure in man by Leonard Hill.

Dr. Frank P. Norbury of Jacksonville, Ill., was recently appointed superintendent of the Kankakee Hospital for the Insane. He will succeed Dr.

James L. Greene, whom Governor Deneen made the alienist member of the State Board of Control of the States Charitable Institution.

The New Medical Practice Act of Washington State provides for issuing licenses of three forms. "First, a certificate authorizing the holder thereof to practise medicine and surgery; second, a certificate authorizing the holder thereof to practise osteopathy; third, a certificate authorizing the holder thereof to practise any other system or mode of treating the sick or afflicted not referred to in this section." In order to obtain a license one must present a diploma from a legitimately chartered school of the system he proposes to follow, besides testimonials of good moral character, etc. The applicant for a license from an examination must be examined on the following subjects: Anatomy, histology, gynecology, pathology, bacteriology, chemistry, toxicology, physiology, obstetrics, general diagnosis, and hygiene. All applicants must obtain an average of not less than 60 per cent. on each of these subjects.

At the July examination 112 physicians presented themselves for examination; of these 76 were successful. Since a new law cannot be retroactive, provision was made in the Act for licensing without examination practitioners of the second and third class, who could comply with certain requirements, specifying the number of years they must have been in practice previous to this time, or the number of years and the months of each in which they had studied in a legitimately incorporated school teaching the system of treatment they proposed to follow. Under this feature of the law, there were 337 applicants for license, the majority of whom were osteopaths, the remainder comprising an extensive collection of systems and forms of treating the sick. Of these, 178 received licenses to practise osteopathy. About 100 of those whose applications were refused have brought suit against the board to compel it to issue them licenses to practise.

Examination of School Teachers.—The Lawrence, Kansas, School Board has adopted a rule that all school teachers, from the superintendent down, must submit to a physical examination and present a physician's certificate as to their good health before beginning their work in the schools.

New Embalming Law in Minnesota.—The State Board of Health of Minnesota has announced a new law relating to embalming. By the law embalming fluids must contain five per cent. by weight of formaldehyde gas and no poisonous matters such as chloral, arsenic, zinc, or mercury. This law is of importance in medicolegal work as it eliminates the danger of embalming preventing determination of the presence of poisons in the stomach of cases of sudden death.

Bequests.—By the will of the late Mr. Benjamin Ellis Martin of New York the Darrach Home for Crippled Children is to receive the sum of $10,000. The Mary Hitchcock Memorial Hospital of Hanover, N. H., received $5,000 by the will of the late Stephen M. Crosby of Boston. The Allegany General Hospital has received $20,000 from the late William H. Singer of Pittsburg.

The Stanford Medical Department, formed by a consolidation of the Leland Stanford, Jr., University and the Cooper Medical College, was formally opened at an assembly held at Stanford University on September 8, 1909. The principal address was delivered by Dr. Henry Ashbury Christian, the dean of the Harvard Medical School, who spoke on the subject of "A Career in Medicine, and Present Day Preparation for It."

The Oakland College of Medicine, situated at Oakland, California, has founded a chair in Tropical Medicine. Dr. Creighton Wellman has been appointed to the professorship of the new department.

The San José General Hospital was opened at San José, California, on September 3, 1909. The hospital at present has accommodations for 18 medical and obstetric cases. A surgical division will be added in the near future.

The Butterworth Hospital Dispensary was opened in Grand Rapids on September 8, 1909, in connection with the Butterworth Hospital of that city. The establishment of this free dispensary was made possible by the generosity of Mr. John Widdicomb who donated the furniture necessary to equip the dispensary.

Belmont Hospital.—It has been reported from Hempstead, L. I., that a new hospital is to be given to that town by Mrs. O. H. P. Belmont, in memory of her husband, to be known as the Belmont Hospital.

The City Hospital of Nashville has announced the following appointments to its visiting staff: From Vanderbilt University, Drs. Lucius E. Burch, James Handley, and George H. Price; from the combined medical departments of the University of Nashville and Tennessee, Drs. Charles Brower, R. O. Tucker, and C. E. Brush.

The Michigan State Medical Society, at its annual meeting in Kalamazoo on September 15 and 16, elected the following officers for the ensuing year: *President*, Dr. J. H. Carstens, Detroit; *First Vice-President*, Dr. V. Tupper, Bay City; *Second Vice-President*, Dr. E. H. Webster, Sault Ste. Marie; *Third Vice-President*, Dr. J. F. Breakey, Ann Arbor; *Fourth Vice-President*, Dr. E. M. Eccles, Blissfield; *Secretary*, B. R. Schenck, Detroit; *Treasurer*, Dr. W. S. Anderson, Detroit. Bay City was selected as the place for holding the next annual meeting.

The International Esperanto Congress met this year, during the second week in September in Barcelona. An attendance of 1300 delegates of 33 nationalities was reported. The next congress will be held in Washington, D. C., in August, 1910, which seems a queer time of year for a meeting in Washington; but perhaps the delegates are used to a hot time at their meetings. The newspapers state that if the Esperantists show any backwardness in announcing their intention to be present at this congress an American delegate will charter a steamship and bring them over, volonte, malvolonte.

The Wyoming State Medical Society at its annual meeting held at Cheyenne, September 2, 1909, elected the following officers: *President*, Dr. N. D. Nelson of Shoshoni; *Vice-Presidents*, Dr. C. E. McCallum of Laramie, Dr. S. W. Johnson of Newcastle, and Dr. J. J. Fossler of Sheridan; Treasurer, Dr. W. A. Wyman of Cheyenne; Secretary, Dr. W. H. Robinson of Sheridan.

The Rutland Medical Reporting Club was organized in Rutland, Vt., on September 9, 1909, the purpose of the club being the stimulation of its members to more extensive reading of the current

medical literature. The following officers were elected: *President*, Dr. M. R. Crain; *Vice-President*, Dr. W. W. Townsend; *Secretary-Treasurer*, Dr. R. E. Smith.

An International Congress of Otology will be held in Boston, in August, 1912. The *Boston Medical and Surgical Journal*, which makes this announcement, states that Dr. Clarence J. Blake of that city has been made president of the Congress.

Obituary Notes.— Dr. William Thayer Smith of Hanover, N. H., died at his home on September 17, 1909, aged 71 years. Dr. Smith received the degree of A. B. from Yale University in 1860 and that of A.M. in 1874. The degree of M.D. was conferred upon him by Dartmouth College in 1878 and by New York University in 1879, and that of LL.D by Dartmouth in 1897. In 1885 he was made Professor of Physiology at Dartmouth, in 1896 Dean of the medical school, and in 1907 Professor Emeritus of Physiology and Professor of Clinical Surgery. He was the author of several text-books, especially of an elementary character, and was a member of the American Medical Association and the American Academy of Medicine.

Dr. G. D. Munger of Oklahoma City died at his home on September 4, 1909, aged 68 years. He was a graduate of the College of Physicians and Surgeons of St. Louis in 1884. Dr. Munger served through the Civil War, rising from the ranks to a captaincy. He was the pioneer physician of Oklahoma City, having gone there in 1889.

Dr. David Finney Stuart of Houston, Texas, died at his home on September 8, 1909, at the age of 76 years. Dr. Stuart was a graduate of the Jefferson Medical College. He served through the Civil War as brigade surgeon of Granberry's Texas Brigade, and since 1867 had practised in Houston. During that time he was chief surgeon of the Houston and Texas Central Railroad, and of many other systems in Texas. He was also at one time president of the Texas Medical College and of the Texas State Medical Association.

Dr. Henry T. Barstow of Boston died at his home on September 7, 1909. He was a graduate of Harvard University in 1880 and of the Harvard Medical School in 1884, and a member of the Massachusetts Medical Society.

Dr. Charles T. Newkirk died September 16, 1909, in Bay City, Mich., aged 68 years. He was Major and Brigade Surgeon U. S. Volunteers. He went through several yellow fever epidemics in South America, besides being a Volunteer Army Surgeon in the Cuban War. Besides also being a member of the Board of U. S. Pension Examining Surgeons, he was an active Railway surgeon and belonged to the American Medical Association, Michigan State and Bay Co. Medical Societies. He is survived by a widow and two children, Dr. Harry A. Newkirk of Iron Mountain, Mich., and Mrs. A. S. Crockett of London.

Dr. Truman S. Sumner of Brooklyn died at his home September 17, 1909, aged 62 years. He was a graduate of the Medical Department of the New York University in 1874 and had been on the staff of the Bellevue Hospital and the Hospital for Ruptured and Crippled. Dr. Sumner retired from practice several years ago.

Dr. Clarence Stephan Perry of Brooklyn died at his home on September 16, 1909, at the age of 44 years. Dr. Perry was a graduate of the Long Island College Hospital in 1885 and a member of the Kings County Medical Society.

Correspondence.

CARE OF THE DEFECTIVE CHILD IN NEW YORK.

To the Editor of the Medical Record:

Sir:—Will you grant me space in which to make a statement in reply to your editorial on "The Defective Child," printed in the issue of August 28, 1909. This statement may seem as "tardy" as New York is claimed to be, but is so merely from the fact that I was away from town and did not have access to the Medical Record until my return.

New York has been doing some good work for the defective child for several years past, and especially for the past three years. These children are being cared for as fast as they are presented, and the necessary teacher can be secured. I have been surprised at the lack of knowledge on the part of many of our physicians in this city regarding the work done, and it may be to the point to state that medical examinations of mentally defective children are being conducted regularly in each borough of the city as the need arises. Classes are formed when a sufficient number of children are found in a locality to warrant this.

The conditions surrounding many of these classes are very good; the appointed teacher must have special qualifications, *i.e.* besides her regular license No. 1 and several years' experience with the normal child she must have made some special preparation for this particular work by special courses of study on the physiology and psychology of the defective child, and attendance at some institution or school for feebleminded children. Many of the teachers employed for these classes, called ungraded classes, are women of the best type and of excellent ability.

The classes are small in number, fifteen pupils being the number allotted to each teacher. We have nearly one hundred of these classes in the system at present, some in each borough, but the major number are to be found in Manhattan and Brooklyn. As far as possible every effort is made to gain the interest and consent of the parents to have remedial physical defects treated. In some instances the results have been very gratifying, in others there have been discouragements. The City Superintendent of Instruction, Dr. William H. Maxwell, is keenly interested in furthering this work, and were it not for his able support and kindly interest the work would never have grown to its present proportions.

An inspector of ungraded classes, Miss Elizabeth E. Farrell, appointed as a result of competitive examination and who has studied the problem both in England and Germany, is at work constantly, furthering the establishment of these classes in every way possible. We are conversant with the excellent work done in Germany and in England, but the conditions in cosmopolitan New York furnish a very difficult problem, and existing conditions must be met as we find them. The comparison between the German Empire and the city of New York seems hardly a fair one; two hundred and thirty schools in *one hundred and fifty* German provinces are hardly comparable to the needs of *one* city, even though that one is the world's second city. It is perhaps an interesting fact that of all the children reported and examined last year the largest number were foreign, and Germany was second on the list, Russia alone outranking her in number. American-born children of American parents found eligible for the ungraded classes form but a small percentage.

Isabelle Thompson Smart, M.D.,
Medical Examiner Mentally Defective Children, City of New York.

THE FOWLER POSITION.

To the Editor of the Medical Record:

Sir:—In reading Dr. Dorland's article on "Some Practical Aspects of the Surgery of the Peritoneum," appearing in your issue of September 18, 1909, I note that the author states in regard to the "Fowler position" that "the wave of improvement rolls on" and that "McGuire's suggestion of the elevation of the head of the bed," made by him in an article March 8, 1908, "will obviously meet these objections." In justice to Dr. Fowler, whose house surgeon I was from July 1, 1900, to January 1, 1901, at the M. E. Hospital in Brooklyn, I wish to say that Dr. Fowler, in all cases where he

used his position, secured it by elevating the head of the bed, and never used the semi-sitting posture, so McGuire's suggestion is not new.

C. F. Buckley, M.D.

Brooklyn, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CARE OF FEEBLE MINDED—ENTOMOLOGICAL RESEARCH AND TROPICAL DISEASES—MIDWIVES' ACT—BARBADOS REPORT ON YELLOW FEVER—BOARDING OUT OF PATIENTS—ITEMS—OBITUARY.

London, September 3, 1909.

The Home Secretary, Mr. H. Gladstone, on Tuesday received a deputation of gentlemen interested in the care of the feeble-mindd. Important suggestions were urged and received with sympathy. One of these, relating to inebriates, deserves special notice, as it was stated by Dr. Ramsay that in one reformatory, by keeping the patients at work as part of the treatment, he had been able to send out 25 per cent. to lead the lives of industrious citizens. Mr. Gladstone told the deputation that some of the anomalies and deficiencies they had pointed out ought to be dealt with at the earliest possible date. But, of course, there were difficulties, and these were in proportion to the scope of the subject and the public issues involved, as well as in the private interests concerned and the ever-pressing question of cost. All agreed, he said, that the only remedy was legislation, and the earlier it came the better. Then he went on to say that the report of the Royal Commission covered very wide ground, so that it might be necessary to deal with it, not as a whole, but in parts. He had communicated with the Lord Chancellor, who regarded the question of supreme importance and would confer with him as to the best line of action. All this seemed to be leading up to announcing immediate action, but was followed instead by the impotent conclusion that he had regretfully to abandon the hope of introducing a bill this year, but he hoped and trusted that a practical effort might be possible next year, and he was sure that the Government, in any action they might then take, would follow the lines of the Royal Commission's report.

The Colonial Office is reaping a good deal of credit for appointing the African Entomological Research Committee. It is recognized that a decided move in advance has been made in the campaign against tropical diseases. The great tradition initiated by Mr. Chamberlain, when Colonial Secretary, of recognizing the value of science in assisting the spread of civilization has been followed by his successors in office. Official support has been of the utmost value to the scattered workers in Africa and the schools of tropical medicine have promoted widespread research and propagated the knowledge thereby acquired. Both these schools, as well as the universities and other bodies, are ably represented on the new Research Committee. A small sum has been voted by the Colonial Office and will no doubt require to be supplemented as the work proceeds, for the scientific societies of this country have no funds to devote to it. We are much behind other nations in the help afforded to science or learning. In France societies devoted to such work almost invariably enjoy a subvention from the government or the municipality—often from both—while here they have to depend on the subscriptions of members. I am told that on your side science is more generally recognized, and as to entomology that each of the States of the Union has an official expert to whom farmers and others may apply for advice. Our new Research Committee will be largely concerned with agriculture as well as medicine; sub-committees have already been arranged to deal with insects in relation to (a) diseases of men and animals, (b) plants. It is also intended to issue at intervals a bulletin or reports of the results accomplished. In the great work which has been carried on during the last few years there has been a certain lack of coordination, which will disappear under the new organization. In this great work the part taken by the Liverpool Tropical School has been most prominent. Expedition after expedition has been sent out by this school, stimulated by the zeal of Sir Alfred Jones and supported by the mercantile shipping world. So valuable has its work been that it has attracted attention in other countries, and Sir A. Jones says that both by sympathy and money it has been largely helped from abroad. He also declares that for further progress more money is needed and if supplied will be used to "kill the flies and so prevent people being bitten." Sir Patrick Manson, Professor Ronald Ross, Sir Rupert Boyce, and other recognized authorities have publicly expressed gratification at the new step taken and will all be more or less engaged in promoting it. Mr. Robert Newstead, M.Sc., lecturer on economic entomology and parasitology in the Liverpool School, says that school has kept in close and constant touch with students and others engaged in research and assisted them as far as possible in identifying material of all kinds in relation to medicine and agriculture. He looks to the new committee to be the future advisory board to those at work in the tropics, and he expects that in return for assistance given in the past both schools will receive material which will help them in teaching other students.

I mentioned last week that Sir A. Jones has determined to equip a branch in the Canary Islands. Dr. Wilfred Parsons, who is to be in charge, after considerable experience as residential officer in hospitals, entered the Royal Army Medical Corps in January, 1905, spent two years in India, and afterward held an appointment in the Persian Gulf.

A report of a departmental committee on the Midwives Act, appointed last December, has been issued, and expresses rather more satisfaction than several practitioners entertain. But these gentlemen should remember that they have only their own apathy to thank, or, in some cases, their pride, for the condition in which they find themselves placed. They were warned at the time that, led by consultants who did not practice midwifery, they were assenting to something like the establishment of an inferior order, and in many places this is the result. The certified midwife takes the cases and the doctor is only called in when danger or difficulty appears—and then he is seldom paid.

The committee reports that an adequate supply of midwives is a matter of organization and no subvention by the State is required. They advocate the establishment of county nursing associations to cooperate with local supervising authorities. The committee thinks the powers of County Councils should be extended to enable them to charge on their funds contributions for training midwives for their areas. Boards of guardians, too, are to be authorized to subscribe and all facilities be given by such authorities toward utilizing their institutions as training centers. More examination centers and more women examiners are suggested to reduce the cost of training and give confidence to nervous candidates. Clearly it is desired by this committee to flood the country with midwives to the ruin of the poorer medical practitioners. A prosperous family doctor may willingly give up the poorer class of midwifery cases, but the struggling ones would be glad to take them. The Poor Law authority should pay the doctor who comes to the aid of the midwife in emergency, and charge the fee to the patient as a loan. It is recommended to enlarge the Central Board, and of three new members to give one to the British Medical Association, though as the appointment will be arranged by the Council the general practitioners need expect no consideration of their position.

The Colonial Secretary, at the request of the Governor of Barbados, has issued a statement as to the epidemic of yellow fever in the island, which is now ended. The first case was reported in December, 1908, prior to which the colony had been free from the disease for twenty-six years. The last case was on the 8th of April last. Altogether, eighty-six cases were notified. Of those attacked thirty-two were whites with fifteen deaths, and fifty-four colored with twenty-one deaths. The estimated population of the colony is 194,477. The death rate for six months ending in May and the average rates for the same six months in the preceding five years were: 1908-1909, 10.9 per 1,000; 1907-1908, 10.8; 1906-1907, 11.7; 1905-1906, 10.8; 1904-1905, 12.5; 1903-1904, 9.4.

The Local Government Board yesterday sent a letter to port sanitary authorities and certain riparian authorities informing them of the movements of cholera and the necessity of taking precautions against its entrance. They also request the medical officers to be furnished with a copy of the letter

The Coventry Hospital is trying a plan of boarding out some of the patients who are sufficiently convales-

cent to make room for more urgent cases in the wards, but over whom it is desirable to retain medical supervision. They are sent to farm houses in the country where the tenants are willing to receive them on moderate terms.

Yesterday Mr. Le Champion called at the London Hospital to see the working. He was shown over the wards and left £1,000 for the general fund and a further £500 to establish a cot in memory of his mother. The hospital would be glad of more such visitors.

A verdict of accidental death was returned last Friday in the case of Dr. Dalrymple, who was cycling home from a patient at Birmingham, where he had been locum tenens for about a week. He passed one tramcar and was killed by another coming from the opposite direction.

Mr. John Bowes of Herne Bay, who had for some time retired from practice, has died at the age of 75. He was M.R.C.S. of 1858 and an ex-president of the Kent and Canterbury Medical Society.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

THE HOOKWORM COMMISSION—THE LOUISIANA LEPER COLONY—SERUM WORK IN THE TROPICS—THE CHOLERA—MEDICAL IMPRESSION OF RELIGIOUS PILGRIMAGES—PERSONALS.

MANILA, P. I., July 19, 1909.

THE Hookworm Commission, of which mention was made recently, which was composed of representatives of the Bureau of Science, the Philippine Medical School, and the Bureau of Health, and operated at Taytay for the purpose of making a sanitary survey of a typical Filipino town, with special reference to the incidence of intestinal parasites, discontinued work early in June, because many of its members had either to return to their positions as instructors at the Philippine Medical School or sever connection with the work for some other reason. It was very unfortunate that the examination of all the inhabitants of the town could not be completed; but it is of interest to note that of the 1,000 examined it was found that over 10 per cent. were suffering with uncinariasis, and that 95 per cent. had some form of intestinal parasite.

In order, however, that this work might be continued in the Philippines, the Bureau of Health immediately put another commission in the field under the direction of Medical Inspector Rissler. This commission will confine itself entirely to intestinal parasites, and will operate in the vicinity of Las Piñas, in Cavite Province, which has a sandy soil, and in this respect differs from Taytay, which has a clay soil. Up to the close of the fiscal year, June 30, 1909, 623 cases had been examined, and it was found that 14 per cent. of the males and 10.6 per cent. of the females were infected with hookworms. In the nearby town of Parañaque, which is also built upon sandy soil, a total of 159 persons were examined, of whom 76 males showed a percentage of 18.4 and 83 females of 12. From the foregoing it will be apparent that more males than females harbor the hookworm, and that the percentage of infection was slightly larger in sandy soil than in clay soil. The figures, of course, are entirely too small to permit any definite conclusion being drawn; but they do show the importance of continuing this work on a large scale in the Philippines and taking the necessary measures for the elimination of the parasite.

The regular monthly meeting of the Manila Medical Society was held on the evening of July 7 in the rooms of the Philippine Medical School.

A paper was read by Dr. Heiser, entitled "The Louisiana Leper Colony," in which he gave a brief description of the Louisiana State Colony, which is located at Iberville Parish, about 80 miles north of New Orleans. It appears that about 45 lepers were confined in this institution, and that the majority of them are white Americans, who have been recruited from the better classes of population. He stated that the disease did not appear to be as severe in the Louisiana lepers as in the Philippine Islands. One noticeable difference is the fact that the Louisiana lepers seemed to be severely affected with leprous eye involvements, particularly iritis, which condition is seldom encountered in the Philippines. Special stress was laid upon the apparent cures which had been made in Louisiana by the chaulmoogra oil treatment, and the improvement which undoubtedly took place in those lepers who took the oil regularly.

The next paper, entitled "A Case of Embryotomy," was read by Dr. Roxas.

The next paper, entitled "Serum Therapy," was read by Dr. E. H. Ruediger, the official in charge of the manufacture of serums and vaccines at the Bureau of Science in Manila. He gave a brief description of the manner in which serums are prepared, and stated that the serum work in the Philippines was not materially different from that which is carried on in other parts of the world. No special climatic difficulties were encountered.

During the past week cholera appeared in a threatening manner over widely scattered sections of the Philippines. Cases in rapidly increasing numbers commenced to occur in Isabela, Cagayan, Tarlac, Pampanga, Bulacan, Albay, Camarines, Samar, Leyte, Oriental Negros, and Cebu. One case occurred in Manila. The infection in Albay and the Camarines was the first, so far as is known, that has taken place in those provinces since 1904. It has been found in the Philippines that usually when the disease appears in a section which has been free for a few years it apparently spreads with greater rapidity than in those sections in which it has been more or less prevalent. This is held to indicate that the occurrence of the disease in a community perhaps gives a certain amount of immunity, and that there is less susceptible material.

It is presumed that the disease was carried to Albay in February as a result of the transfer of a company of Constabulary from an infected district in Samar to Ligao. Whether it was carried by Constabulary by "cholera carriers" or whether a mild case was imported through the large number of women that followed the soldiers to Albay for a number of weeks after the company itself was moved, is not known. However, the first cases of the disease appeared in a small town which is situated a few miles below Ligao on the same river on which Ligao is located, and the next case occurred at Daraga, which is also situated farther down on the same river. The sudden appearance of cholera in the interior of the province of Albay among persons who had not been out of the province for many weeks was at first difficult to explain; but it is believed that the Constabulary company and their camp followers at least throw some light upon the case.

The large religious pilgrimage which takes place annually to Antipolo, and at which sometimes as many as 10,000 persons are present in one day, was very carefully supervised this year, and no infections occurred. A number of cases of diarrhea and other suspicious cases were encountered, but they were promptly isolated and no spread took place. As in the times of old, the religious gatherings are still one of the greatest causes for the spread of cholera in the Philippines. The sudden appearance of the disease over so large an area in the Cagayan Valley has been directly traced to the large religious gathering which took place at Piatt. Cholera appeared among the participants, whereupon they commenced to scatter in all directions, and consequently the disease made its appearance simultaneously in a great number of towns.

Assistant Surgeon H. J. Nichols, U. S. A., who has been a member of the Army Board for the Study of Tropical Diseases, has completed his detail and sailed for San Francisco on the United States army transport *Logan*, which left Manila July 14.

Passed Assistant Surgeon Pettyjohn, United States Philippine Hospital and Manila Hospital Service, who has been quarantine officer at Iloilo for the past two years, has been relieved by Assistant Surgeon Olesen, Philippine Hospital and Manila Hospital Service, and sails for San Francisco July 21 on the steamship *Manchuria* in pursuance of official orders.

SIXTEENTH INTERNATIONAL MEDICAL CONGRESS.

(Special Report by Our Vienna Correspondent.)

TUBERCULIN—PERICARDITIS EPISTENOCARDICA—ABDOMINAL ARTERIOSCLEROSIS—ANEMIC MURMURS—POLYCYTHEMIA—OBESITY—PATHOLOGY OF LEUKEMIA—AMEBIC DYSENTERY.

IN the section on internal medicine Pel of Amsterdam in a paper on the treatment of pulmonary tuberculosis by means of tuberculin said that it was difficult to judge of its real value. Spontaneous changes in the patient, the effect of suggestion, the possibility of spontaneous cures, and the difficulty in diagnosis must be considered. Theo-

retically, by raising an active immunity it should tend to produce cures, but the tuberculin varied in itself and in its effect on individual animals. Tuberculin should be derived from the patient's own organisms. Opinion as to its therapeutic value varied widely. It should not be used as a prophylactic. As individual susceptibility to tuberculin varied greatly, cases treated with it must be carefully watched by competent physicians. In any case the treatment was not danger-free. Tuberculin was a dangerous friend, and its general use in practice would cause more harm than good. If properly used it offered us a valuable therapeutic agent.

Dr. Maximilian Sternberg of Vienna spoke on the syndrome first described by Kernig, pericarditis following angina pectoris attacks, and described his experience with it. This was an important syndrome of great diagnostic and prognostic value. The condition consisted in the occurrence of myomalacious foci, either superficial or extending to the surface from large deeper foci, which caused a pericardial exudate. Chronic aneurysm of the heart was especially frequently associated with such a pericarditis. If the condition did not cause immediate death, the attack might cause a sort of cure of the angina pectoris, at least to the extent that the anginal attacks might be less frequent or for a time entirely absent. A knowledge of this pericarditis epistenocardica was of importance in the understanding of the noninfectious pericarditides of middle and advanced age, in the prognosis of angina pectoris, and in the diagnosis of chronic parietal aneurysm of the heart, in that by the aid of this syndrome one distinguished, from the general picture of disease, the occurrence of myocarditis and myocardial degeneration.

Professor Kolman Müller of Budapest said that arteriosclerosis of the gastrointestinal tract was a very common condition—more so than previously appreciated. The important diagnostic point was attacks of abdominal pain concomitant with lesions or functional injuries to the heart or blood-vessels. It was not known whether the pain was due to cramps of the vessels or to a neuralgia of the sympathetics. The disease was more common in men than women. Vasodilators were beneficial in the attacks. With the knowledge of their arteriosclerotic etiology many gastrointestinal conditions could be successfully treated.

Professor S. E. Henschen of Stockholm said that the systolic anemic murmurs were but poorly understood. He discussed the physical characters of such murmurs, and said that such murmurs signified a dilatation of the heart, and that the loudness of the murmur was in proportion to the extent of the dilatation. The relative insufficiency occurred when the blood current was under a pressure not sufficient to close the valves, when the valves were not normal, when the papillary muscles were weak, or when the mitral orifice was dilated or the mitral ring weak. Febrile murmurs were closely related to the anemic. In septic fever and typhoid the murmur was usually weak and soft, but by percussion the heart was found dilated. Rougher murmurs occurred in diphtheria and influenza; a similar dilatation murmur having nothing to do with endocarditis might occur in acute articular rheumatism. In chorea murmurs were more commonly endocardial than spasmodic. Pericardial synechiæ often caused strong, rough, systolic murmurs when no valvular lesion could be found at autopsy. So also could cardiac hypertrophy. In paroxysmal tachycardia (typhoid and diphtheria) the murmur disappeared with the subsiding of the tachycardia. The murmurs of Basedow's disease and chronic nephritis belonged to this same class. The patients should be kept in bed during the continuance of the symptoms of insufficiency.

Polycythemia rubra or erythrocytosis was, according to Professor Senator, either a relative or an absolute increase of the red cells. Physiological polycythemia occurred through loss of water, after eating a rich protein meal, during convalescence from anemias, in the new-born, in a rarefied atmosphere, accompanying artificial dyspnea, and during hibernation. Pathological polycythemia was seen with thickening of the blood from sickness, with cyanosis from congenital heart disease or venous stasis, with intoxications or infections preceding hemolysis, rarely in other diseases with unknown blood changes, and in nervous diseases. Polycythemia megalosplenica, Vaquez's disease, in which the polycythemia occurred in middle life and was associated with cyanosis and an enlarged spleen, was due to a primary unknown disease of the bone marrow. The therapy for it consisted of vegetarian diet and bleeding. In polycythemia hypertonica (Geisböck), with a high blood pressure but no splenic tumor, the therapy was the same. In two cases thyroid iodine had a favorable influence.

Professor Carl von Noorden of Vienna discussed the subject of obesity. He said that most cases depended upon the fact that the calorie content of the ingested food was greater than that required by an average man under the same external relations, or that the energy demanded by muscular activity was abnormally low (overfeeding or inertia obesity), or else that the laying on of fat was due to some delay of metabolism. By either of these protoplasmic processes a certain amount of material was spared. The abnormal reduction of required energy in such cases could be dependent upon special properties of the protoplasm or abnormal regulation of the glands which had internal secretions. Hyperplasia or hyperfunction of the thyroid caused increased oxidation, as in Grave's disease. This, as well as the ingestion of thyroid substance, caused loss of weight. Hypoplasia, atrophy, degeneration, or extirpation of the thyroid led to reduced oxidation, myxedema, and obesity. In premature atrophy, degeneration, or extirpation of the generative glands, obesity often occurred. Extirpation of the pancreas, according to Falto, produced decided obesity. In acromegaly, that is, hyperplasia of the hypophysis gland, there was usually increased oxidation and loss of weight, despite polyphagia. In hypophysis tumors there was usually obesity called degeneratio adiposa genitalis (typus Fröhlich), in which the secondary sexual characteristics of the man assumed the female type, and of women the infantile. We must assume that the internal secretion of the thyroid alone stimulated oxidation directly, but that its function might be regulated by the other organs. A chemical relation between the thyroid and the pancreas had been demonstrated. Constitutional obesity, slowing of metabolism, was dependent upon a weakening of the specific function of the thyroid, which controlled the transformation of energy. He distinguished "secondary thyrogenic obesity," in which the functional anomaly of the thyroid was caused by influence of other organs as the pancreas, ovary, hypophysis, suprarenals, thymus, pineal body, etc., and "primary thyrogenic obesity," in which the anomaly of function was dependent upon an intrinsic lesion of the thyroid itself, atrophy, degeneration, functional weakness, etc. The relation between obesity and reduced transformation of energy by the thyroid was only a hypothesis, but was based on clinical and experimental facts.

Dr. Wilhelm Ebstein of Göttingen discussed the pathology of leukemia, which he said might be acute or chronic. The acute form usually lasted about two months, at most six months, and might attack the healthy or follow infections, malaria, syphilis, or repeated pregnancies. The onset was sudden, often with a chill, with headache, pain in the joints and legs suggesting rheumatism, with a typhoid state and enlarged spleen, with tonsillitis and cervical lymphadenitis, following which scorbutic symptoms and hemorrhages gave the diagnosis of leukemia. With the hemorrhages appeared enlarged, hard, and tender lymph glands; the mediastinal glands and thymus were also enlarged. Splenic tumor was rare in the acute form. The tonsils were inflamed, phlegmonous, and often gangrenous. Loss of appetite occurred early; diarrhea later, from intestinal lymphadenitis. Lymphatic deposits in various organs caused hemorrhages on slight trauma. The teeth loosened, and salivation symptoms occurred. Destruction of lymph tissue in the vessels produced scattered hemorrhages, thrombosis, skin hemorrhages, paralysis from hemorrhage into tendons, blindness, deafness, etc. Microscopically the blood was not white, the characteristic leucocytosis developing only in the course of the disease. The prognosis was hopeless, death occurring from hemorrhage or secondary infection. The diagnosis depended upon the blood picture with the erythocytes in embryonal stages. The chronic form lasted one and a half to two years. In the early stages there were often remissions, either spontaneously or under arsenic. The question of the infectiousness of the disease was still obscure. The leukemia of pregnancy was not transmitted to the embryo, but living children could as a rule be obtained only by premature labor. Among exciting causes of leukemia were sepsis, influenza, pneumonia, erysipelas, tuberculosis, especially miliary tuberculosis, and, much more rarely, gout.

George Dock of New Orleans reported on the results of treatment of cases of amebic dysentery. Following the administration of ipecac, the amebas disappeared from the feces within a few hours, the stools became less dysenteric, and in a short time normal. There was continued good health, with no amebas in the feces up to four years and a half after treatment. In some cases previous treatment with quinine enemata, intestinal antiseptics, and other drugs had been carried out carefully, but without success. The ipecac was given in pills covered with salol. The

dose was gm. 4.0 to 7.0 a day, one pill every hour, or gm. 2 to 4 twice a day for one, two, or three days, according to the severity of the case. Following the use of salol-covered pills, vomiting occurred but rarely, and opium was not necessary. The results should be controlled by examinations of the feces, and by the use of the sigmoidoscope or proctoscope. Enemata or local medicinal treatment of the colon might be used in addition to the ipecac.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 9, 1909.

Simple Inspection of the Eyes as an Aid in General Diagnosis.—H. B. Stevens makes a plea for a more thorough inspection of our patients' eyes in general diagnosis. He gives an outline of the anatomy and physiology of this organ, and then passes on to enumerate some of the eye symptoms and signs of various local and general diseases. Nothing new is brought out, but the paper is of value as being a vigorous exhortation to use our eyes more and not to be misled by those variations from the strictly normal which may be compatible with health. Attention is also directed to the parts which border on the eyelid and to the nearness of the brain and other vital structures.

Sudden Deaths in a Synopsis of Twenty Years' Medicolegal Work.—F. J. Canedy analyzes his experience as Medical Examiner in a district of Western Massachusetts. In the course of twenty years he saw 202 cases. Of these 54 were killed by the cars, 33 died from heart disease, 10 apoplexy, 1 from measles, 2 from alcoholism, and 10 from pulmonary hemorrhage. There were 36 suicides, 11 from hanging, 4 from drowning, 8 from shooting, 5 from laudanum, corrosive sublimate, and chloral, each 1, and 1 from throwing himself in front of an engine. The author then gives various facts about individual cases, and says that sudden death comes from circulatory systemic disturbances more often than from all the rest of the other systems of the body combined. Under this general heading special mention is made of fatty and fibroid degeneration of the heart, endocarditis, and arteriosclerosis of the vessels, which probably causes sudden death more often than any other vascular lesion. The fatal change generally begins around the aortic arch and thence spreads. The fragility of the arterial walls may eventuate in aneurysm, rupture of the aorta, thrombosis, or rupture of the basilar artery of the brain, causing in either case sudden death. But the most common fatal cause is angina pectoris from sudden spasm of the coronary arteries.

New York Medical Journal, September 11, 1909.

Treatment of Pruritus Ani.—W. M. Beach considers the pathology and etiology of this condition, and reaches the following conclusions: (1) Pruritus ani occurs in mild and severe forms; mostly in middle life; the mild type with simple pruritus, the severe type with marked eczema and skin changes. (2) Certain aberrations in general metabolism, or in adjacent structures are simply incidental, and should be considered as complications. (3) Intrarectal growths, as hemorrhoids, adenomata, etc., and the presence of parasites are contributory. (4) The distinct pathogenesis of pruritus ani consists of single or multiple burrowings from the anal pockets, emitting a serous or seropurulent substance, which sinus may be complete or blind, and is always accompanied by proctitis, and frequently by cryptitis and small ulcers at the anorectal line. (5) These sinuses when complete are sequelæ to an abscess history, but the origin of the blind recesses is in doubt, and yet it is not unlikely due to an infection by the colon bacillus. (6) The treatment is surgical for the purpose of obliterating the sinuses, correcting a rigid sphincter when necessary, and curing the proctitis and ulceration. (7) Gastrointestinal and general metabolic disturbances must be met by rational measures.

Blood Examination in the Presence of Gangrene.—I. S. Wile refers to the errors of certain observers who have reported on blood counts in certain abdominal infections, errors especially evident in conditions of gangrene attended by no leucocytosis and no increase in polynuclears. Leucocytosis is an index of body resistance, and the relative increase of polynuclear neutrophiles parallels approximately the degree of toxic absorption. Therefore gangrenous conditions of the appendix without much absorption show little or no increase of these cells, while the total leucocyte count may be scarcely altered. Blood examinations afford symptomatic facts, to be interpreted only in the light of the clinical history of the patient. In surgical conditions, as appendicitis, the hematological facts may have corroborative value in determining the time of operation. The operation, however, should never be based merely upon the blood examination. In gangrenous appendicitis, particularly, the blood examination demands most careful interpretation to afford diagnostic aid to the surgeon. Its prognostic value is limited to the time at which the blood was taken for examination. It has no prognostic value for the future pathological developments. Therefore frequent blood examinations are required to keep a record of the prognostic indications of the blood conditions. The indications for operation arise from a consideration of the history, physical examination, and clinical facts elicited. The blood examinations merely supply part of the clinical facts.

Do the Saprophytes, So Called, Produce Toxins Which Have Selective Attraction for the Brain and Nerve Tissue and Thus Cause the Idiopathic Diseases of These Structures?—B. R. Le Roy discusses this question, giving an affirmative answer. Starting from the proposition that a normal person was free from unpleasant odor, and that a diseased person was afflicted with varied odors, and that many diseases are as readily recognized by their odors as by any other method, the first step was to examine into the odors of the nerve diseases in which the writer was most interested, paralysis and the epilepsies. It is well known that all paralytics, without reference to the cause, have an odor that is very peculiar, and peculiar to that disease; no other diseased condition known to the writer will or can produce the same odoriferous emanation that is readily noticed in all cases of paralysis. Again, the odor of paresis is as nothing when compared with the odor emanating from an epileptic! Now, why should these diseases produce such vile odors? What is it about the disease or diseased person that produces these infernal stenches? Surely there must be a reasonable cause, and if so, why not try to discover it, and when found try to remove the cause of the odors, and perhaps the removal might modify or change the course of the disease. The author relates his experience with several cases, removing, by various methods of cleansing, the secretions from the various offensive parts of the body and finding great relief to the nervous symptoms of his patients. The essential feature was a "scrub-bath" of the entire skin with a weak acid solution, vaginal douches, etc.

Journal of the American Medical Association, September 11, 1909.

Disposal of Sputum.—W. J. Manning considers that we are generally too careless in the disposal of sputum, especially in workshops and in hotels, saloons, barber shops, railway stations, and other public places. Signs are up in most of these in every town, cautioning against spitting on the floor and advising the use of cuspidors, but the disposal of the contents of these last is often very faulty. The observing person will see these vessels cleaned near drinking water supplies or roughly dumped in any convenient locality. The type of cuspidor in use in the great majority of cases is faulty, very little attention having been given to ease and thoroughness of cleaning. The repulsiveness of the cleaning operation almost prohibits the worker from putting his hand or sponge in the places that need most of the cleansing. In breaking up the ordinary type of cuspidor he found incrustations in some instances of dried sputum half an inch thick, and, if not dried, in a semisolid putrid condition. He figures the type of cuspidor devised by him for the government printing office use, which permits easy rapid cleaning with a common dish mop and boiling water. The cuspidors are cleaned in a large trough filled with hot water, which destroys at once the bacteria, and the method of cleaning is described in detail. Besides this, an antiseptic is used, potassium permanganate being preferred for reasons of safety and cheapness. Fourteen hundred cuspidors of this pattern are washed and sterilized in the method described at the end of every shift of eight hours in the government printing office. While the conditions there are almost ideal, as befits a great government institution, effective arrangements can be obtained in the corner of any basement of a factory, hotel, depot, or other public building, as the fittings and equipment are very simple and inexpensive.

The Flexner Serum in Meningitis.—F. S. Churchill shows how the use of the Flexner serum has reversed the proportions of deaths and recoveries and greatly reduced the unpleasant sequelæ of the disease. He also gives his own observations of forty-one cases, of which twenty-nine were demonstrated as beyond question due to the meningococcus. In these twenty-nine, thirteen, or 44 per cent., died, but closer analysis shows that lateness of beginning

of the treatment in the disease and lack of proper dosage accounts for the mortality. Hospital patients do better than those treated at home. They can be watched more closely, the serum can be given more persistently and thoroughly, and more exhaustive laboratory investigations as to the blood, etc., can be carried out to guide the treatment. The most striking thing in the cases treated early in the hospital is the high percentage of perfect recoveries without sequelæ and the especially low rate of mortality, it being sometimes as low as 10 per cent. in cases treated within the first three or four days. The course of the disease is materially shortened and the patient is much more comfortable. The increased phagocytosis can be observed with the successive injections. He describes the technique of the method. The injection must be made at the pathological seat of the disease by lumbar puncture. Evacuate 30 to 45 c.c. of the spinal fluid if possible, and, if it is at all turbid, inject an equal quantity of the serum at once, without waiting for an examination. If the bacteriological examination shows the presence of the meningococcus, subsequent injections of the serum should be given. It is better to repeat the dose daily for three or four successive days before stopping the injections, and as a rule it will then be found that the patient is decidedly improving. If the conditions do not improve, repeat the process, and so on until bacteria have disappeared, giving occasional injections until no organisms are found in either smears or cultures. Five cases are reported, two of them illustrated by charts.

The Expression of Cataract in Its Capsule.—H. V. Würdemann describes Pagenstecher's operation, or expression of cataract in its capsule, and quotes that author's definition as the most accurate that has yet been given. He sees nothing specially original in the modifications introduced by Major Smith of Jullunder, India, whose experience of 20,000 operations has aroused so much interest. Würdemann does not deem the purely corneal section acceptable, as it is followed by slow healing, iridic prolapse, distorted pupils, and excessive astigmatism, nor is the operation with iridectomy acceptable on account of iridic prolapse. In his experience the two-fifths sclerocorneal section with conjunctival flaps combined with a very small iridectomy and extraction of the lens, *i.e.* the regular operation less a capsulotomy, in immature and hypermature cataract, is the only all-round satisfactory operation. Würdemann gives the details of the technique, stating that it is no operation for the beginner or the average operator, and gives brief notes of his forty cases. He hints in conclusion that the apparent lessened susceptibility to infection of the Hindoos, as in other less civilized races, and, above all, the fact that these patients disappear from observation, may account for the remarkable success reported by Indian operators. For the final results we must depend on the testimony of those who practise in countries where patients can be more easily followed up.

Alimentary Albuminuria.—H. G. Wells has employed the anaphylaxis test to decide whether the albumin found in the urine in so-called alimentary albuminuria is simply filtrated through the kidneys or is of human origin. Although a few observers report having found evidence of the presence of specific food protein in the urine in alimentary albuminuria by means of the precipitin reaction, yet by the anaphylaxis reaction the results are found quite different. Guinea-pigs sensitized with urine from four healthy persons with experimental albuminuria produced by eating raw eggs, and with urine from two patients with nephritis, reacted typically and severely to subsequent injection of human ascites fluid and not at all to egg white or egg albumin. Wells says, that in view of the extremely minute quantity of protein necessary to sensitize guinea-pigs to the homologous protein, these results speak against the prevalent view that the albumin found in the urine in alimentary albuminuria is the same protein that has been taken in the food. Either it has been altered to the extent of acquiring specific human properties after ingestion and before being eliminated in the urine, or else it is not excreted at all, but injures the kidneys slightly and transitorily by overloading the blood with nitrogenous waste products so that they become more permeable to the normal serum proteins. This last explanation, he says, would seem most probable but for the fact mentioned above of food proteins being detected by several observers by means of the precipitin reaction. This discrepancy between the two tests may be interpreted as meaning that the two methods are not of equal value, or it may be suggested that the precipitin reaction is given by food proteins that have been so altered during absorption and excretion that they will not sensitize guinea-pigs to the original protein. Previously reported experiments, however, show that digestion of proteins quickly destroys their power of reacting with precipitin, while the anaphylactic properties of protein are not lost by digestion for a very long time. In any case, Wells says, there can be no question that in alimentary albuminuria, as well as in nephritis, the urinary proteins are chiefly, if not exclusively, human proteins and therefore presumably derived from the blood and not from food. Whether any unaltered food protein reaches the urine is still in question on account of the statements of the observers who have reported it with the precipitin test. Further studies are needed to clear up this point, both because it is desirable to know just the relation of the two tests to each other and to settle the physiological question whether unaltered food proteins can pass through the intestinal wall. There is some practical importance to this question because at times it might be desirable to know whether the albumin in a given sample of urine comes from the food or the blood. To show the delicacy of the anaphylactic reaction, he reports experiments made with sensitizing guinea-pigs with urine from healthy young men and detecting the presence of albumin when it existed in so small amount that it gave no reaction to the heat or nitric acid tests.

The Lancet, September 4, 1909.

A Possible Natural Enemy to the Mosquito.—J. M. Atkinson writes of his observations in Hong Kong, stating that he has seen flies eating the larvæ of the mosquito. Some of these flies were collected and are figured by the author. They have been identified as belonging to the species *Lispa sinesis*, Schiner, of the family of anthomyidæ or flower flies. A technical description of these flies is given in the original paper.

A Case of Delayed Chloroform Poisoning Treated with Dextrose; Recovery.—The patient of A. A. Weir was a boy of nine years, operated on for appendical abscess, the time of the anesthetic being about forty-five minutes. After the operation the patient was restless and vomited once. Otherwise all went well for forty-eight hours, when the restlessness increased into a maniacal delirium, the patient tearing off his bandages and requiring mechanical restraint. A condition of delayed chloroform poisoning was diagnosed, although vomiting was absent, except as stated, and sodium bicarbonate was given by rectal injection. On the third day the patient was alternately delirious and comatose. The urine was normal in amount, and when tested by liquor ferri chloridi showed the presence of diacetic acid. Acting on a suggestion seen by the author in a medical journal, a solution of glucose, half an ounce to half a pint of milk, was given through the nasal tube and a 10 per cent. solution by the rectum every four hours. Carbohydrate food was given freely. For the next twenty hours all went from bad to worse, the face becoming a deep plum color, the coma deepening, frothy saliva drooling from the mouth, etc. Sweating was profuse and Cheyne-Stokes breathing developed. The pulse remained good, however, and was never above 108, while everything administered was retained. After a few hours the tide turned and the patient began to move his head. In six hours more he was apparently out of danger, and recovery was without incident. The boy had previously taken chloroform for the removal of adenoids, and without any alarming symptoms. The author says that in view of previously reported cases of delayed chloroform poisoning, it is hard to account for the absence of vomiting, which has always been a prominent feature. In fact, it has been the most constant symptom. In his case another noteworthy feature was the slow onset of symptoms.

The Vacuolation of the Blood Platelets: an Experimental Proof of Their Cellular Nature.—H. C. Ross refers to the reported experiments of Moore and Walker in the *Lancet* of July 27, 1907, in which they determined the utility of certain new methods of staining blood cells *in vitro*. This paper described how small, bright, red spots developed in the leucocytes after resting for some time on agar jelly, and it was suggested that the spots might be centrosomes. Recently Ross has found that by following a certain technique (described in full) these red spots can easily and constantly be found in the blood platelets. He found, however, that the spots were not centrosomes, but diffusion vacuoles. If the diffusion of stains into leucocytes is accelerated by heat or an alkali, so as to cause maximum staining without actually killing the cells, then stained liquid also passes into the colloid cytoplasm and remains suspended in it as a red spot. Morphine will also cause extreme vacuolation of the leucocytes. Ross has shown that cells have different coefficients of diffusion, and that in blood cells, approaching death

causes a lowered coefficient. It is obvious that the vacuoles will appear more readily, *i.e.* liquid will diffuse more easily into cells which have a lowered coefficient of diffusion. It is apparent, therefore, that the blood platelets must be cells, or rather must be composed of living protoplasm, for their vacuolation is produced experimentally by the action of poison, as morphine, in causing the gradual approach of death, also lowers the coefficient of diffusion. As all the platelets in a specimen usually become vacuolated, Ross believes that they all belong to one class of cell, derived from one source. In view of the vacuolation, he believes that the precipitate theory of the blood platelets is untenable. He also dismisses the theory that they are the extruded nuclei of red cells. The correct theory, according to him, is that the platelets are fragments of leucocytes. They have the same coefficient of diffusion as these cells and usually contain a few granules which have the same staining rate as those of the leucocytes. When blood is placed on jelly which excites ameboid movements in leucocytes the platelets have been noticed to extrude and retract pseudopodia, and these when separated appear to be identical with the other platelets seen in the specimen.

Berliner klinische Wochenschrift, August 23, 1909.

Monoplegic Syringomyelia.—August Wimmer reports three cases of syringomyelia, involving in each case but one extremity, a form of the disease which is not common. The first case, in a shoemaker aged 38, began with paresthesia in the left thumb, and later progressed to trophic disturbance and ulcerations. Anesthesia then appeared, and a tendency to cyanosis and swelling of the hand. The tendon reflexes were absent, and thermal and pain sense were affected in the left arm. In the second case a student, aged 19, had noticed for a year weakness and coldness of the right hand. There was a definite atrophy of the intrinsic muscles of the left hand. There was no pain. In the third case the left leg was involved, weakness having been noticed for six months. The left leg on examination was seen to be smaller than the right, cold, and showed peroneus paralysis, and hypoalgesia: hypoesthesia to heat and cold occurred in this leg alone.

Pharyngeal and Laryngeal Symptoms of Syringomyelia.—Baumgarten says that laryngeal symptoms in syringomyelia are much rarer than in tabes dorsalis. He has seen but one case in twenty years, which he reports. The patient sought advice for hoarseness without knowing that he had the more serious nervous disease. This is not usually the case, the laryngeal symptoms coming on as a rule late in the disease. Laryngoscopic examination showed that the vocal cords were fixed in the middle line, due to bilateral posticus paralysis. There was a right-sided hemiatrophy of the tongue, and the motion of the right half of the soft palate decreased. Tabes was ruled out, and a diagnosis of syringomyelia made by a neurological examination. Baumgarten analyzes the twenty-seven cases of laryngeal complications of syringomyelia which have been reported. In twenty-four of the twenty-seven there was a paralysis of the vocal cords; in the other three a loss of the larynx reflex and sensibility. In one case analgesia and loss of thermal sensation was noted. Of the twenty-four paralyzed cases one showed bilateral and ten unilateral recurrens paralysis, unilateral recurrens paralysis with posticus paralysis of the opposite side occurred four times, bilateral posticus paralysis four times, unilateral posticus paralysis three times, and unilateral paresis (probably posticus) twice. In three cases the hoarseness came on suddenly, associated with recurrens paralysis. In one of these the recurrens paralysis followed a chronic posticus paralysis. In seventeen of the cases there was paralysis or paresis of the soft palate. These in some cases improved, whereas the laryngeal paralysis does not improve. Atrophy of the tongue was noted in nine of the twenty-seven cases. In one case the atrophy was preceded by thickening. In two cases there was reduced sensibility and heat perception on the atrophied side of the tongue. The lingual atrophy was always unilateral. The sense of smell was rarely examined, but was found to be lost in two cases.

Münchener medizinische Wochenschrift, August 17 and 24, 1909.

The Decrease of the Sensitiveness of Tuberculosis Patients to Tuberculin During Measles.—Grüner calls attention to the liability of measles to light up a latent tuberculosis or to increase a patient's susceptibility to tuberculous infection, and to the fact that Pirquet has shown that during an attack of measles tuberculous children fail to give the skin reaction with tuberculin. The question arises as to whether this is an absolute loss of sensitiveness to tuberculin or merely a hyposensibility. To test this the author investigated thirteen cases of measles in tuberculous children. These were injected with old tuberculin, some in doses of 0.1 mg., some 1.0 mg. From the results which are reported in tabular form the author states that the loss of sensitiveness to tuberculin during measles is only a relative one. Whereas the injection of 0.1 mg. did not give a reaction, the use of 1.0 mg. gave positive results in six of the seven cases. These reactions, however, became more intense after eight days, the time that the effect of the measles wears off. The author states that during measles the susceptibility to tuberculin is reduced at least one thousand times, but returns rapidly after the eighth day. This reduction is not due to an antituberculin. It is more likely due to the loss of the natural reactive power, and consequent defenselessness of the body against the poisons of the tubercle bacillus.

Relation of Albuminuria to the Acidity of the Urine.—V. Hoesslin has studied the relation existing between the acidity of the urine and the amount of albumin and number of casts in cases of chronic nephritis. The acidity of the urine was regulated by giving sodium bicarbonate by mouth. He concludes that albuminuria and casts stand in many cases in direct proportion to the acidity of the urine. In such cases the albuminuria and number of casts decrease or disappear with the reduction of the acidity by the use of sodium bicarbonate. In all cases of albuminuria the estimation of the urine acidity must be made. The dose of sodium bicarbonate must be regulated in each case by quantitative estimation of the albumin and acidity of the urine.

Changes of Blood Pressure under Compressed Air—Schöppner investigated the blood pressure of himself and a coworker under normal atmospheric pressure and then when in air compressed to a pressure of 350 mm. He concluded that the increased atmospheric pressure did not cause a sinking of the blood pressure.

The Use of Marmorek's Tuberculosis Serum Locally.—Schnöller says that the general use of the serum has the following drawbacks: (1) It is greatly diluted by the general blood. (2) Thereby it is distributed over the entire body, and but a very small portion is enabled to act upon the local focus of disease. (3) The rapid flow of the blood prevents the serum from reaching the diseased tissues and remaining there long enough to produce effect. For these reasons the author considered it better in cases of local tuberculous disease to inject the serum directly into the diseased focus, whereby one would expect a stronger and more rapid activity. He reports two cases. In the first the injection of from 2.5 to 3.0 c.c. of the serum caused rapid healing in a tuberculous abscess which had shown no signs of improvement during three months of the usual treatment. The second case was in a patient with advanced pulmonary and laryngeal tuberculosis. In this case one abscess of the rib occurred which broke down and formed an ulcer which showed no signs of healing. Three weeks after the injection of 2 c.c. of the serum the wound was completely healed.

The Diagnosis of Latent Malaria.—Plehn says that three latent periods may be recognized in the course of malaria. The first phase is that after the initial infection and before the first chill. This may last for months, and may be characterized by great nervousness, digestive disturbances, and more or less anemia. Basophile granules may occur in the blood. The second latent period is the best known. This occurs between the acute attacks, and may be called the intermediate latent periods. It may vary from a few days to several weeks. The final latent period of malaria consists of the period after treatment and apparent recovery before a relapse occurs. This may be as long as two years. Plehn says that in all such cases the liver is markedly affected, and that a most important help in the diagnosis of such a case is the presence of urobilin in the urine.

Crypto-Diphtherias.—Abrand says that cases come into every hospital without visible membrane in the throat, which later prove to have been true diphtheria, the membrane being located in the larynx, nasopharynx, trachea, or esophagus. They are discovered late in the disease, when they have been severely poisoned, perhaps diagnosed only by the symptoms of diphtheritic paralysis of the palate, and have already spread the disease to other patients. The symptoms that indicate this state of things are extreme fatigue, loss of weight, rapid pulse, marked swelling of the glands of the neck, with or without high fever.—*Annales de Médecine et de Chirurgie Infantiles.*

MEDICAL LIBRARIES.

II. 1909.

In the following list the name of the library is followed by the post office address, the name of the librarian, and the number of bound volumes. Corrections and communications concerning libraries and applications for copies of the list (with stamp enclosed) may be addressed to the Librarian of the New York Academy of Medicine. Collections of medical works in general libraries, some of them very important, are omitted.

ALBANY—New York State Medical Library, Albany, N. Y., U. S. A. Miss Ada Bunnell. 20,087.

AMSTERDAM—Library of the Netherlands Medical Society, 87 Hoofstraat, Amsterdam, Netherlands. Dr. C. P. Daniells. 25,000.

ANTWERP—Library of the Antwerp Medical Society, Royal Atheneum, 40 Rue van Straalen, Antwerp, Belgium. Dr. Edward d'Haenens. 3,120.

ATLANTA—Library of the Atlanta Medical Library Association, Carnegie Bldg., Atlanta, Ga., U. S. A. Miss Rankin. 2,000.

BALTIMORE—Library of the Medical and Chirurgical Faculty of Maryland, 1211 Cathedral street, Baltimore, Md., U. S. A. Miss Marcia C. Noyes. 17,533.

Library of the Department of Medicine of the University of Maryland, Baltimore, Md., U. S. A. Dr. Eugene F. Cordell. 9,000.

Library of the College of Physicians and Surgeons, Calvert and Saratoga streets, Baltimore, Md., U. S. A. Miss Ethel I. Disney. 1,189.

Johns Hopkins Hospital Library, North Broadway, Baltimore, Md., U. S. A. Miss Minnie W. Blogg. 9,521.

Johns Hopkins Medical School Library, Monument and Washington streets, Baltimore, Md., U. S. A. Dr. M. L. Raney. 5,750.

BEIRUT—Medical Library of the Syrian Protestant College, Beirut, Syria. Rev. Harvey Porter. 1,859.

BELFAST—Library of the Ulster Medical Society, College Square North, Belfast, Ireland. Dr. W. L. Storey. 2,000.

BERLIN—Library of the Kaiser Wilhelm Academy, Friedrichstrasse, 140, Berlin, N. W., Germany. Dr. A. Hiller. 67,000.

Library of the Berlin Medical Society, Ziegelstrasse, 10-11, Berlin, N. W., Germany. Dr. Ewald. 50,000.

Library of the Society of Internal Medicine, Schoeneberger Ufer 11, Berlin, Germany. Dr. Max Ph. Meyer. 9,000.

Library of the German Surgical Society, Ziegelstrasse 10-11, Berlin, N. W., Germany. Dr. Fischer. 24,860.

Library of the National Health Office, Klopstockstrasse, 18, Berlin, N. W., Germany. Dr. Wurzburg. 57,000.

BIRMINGHAM—Library of the Birmingham Medical Institute. Edmund street, Birmingham, England. Mr. T. G. Johnson. 14,300.

BOSTON—Boston Medical Library, 8 The Fenway, Boston, Mass., U. S. A. Dr. John W. Farlow. 66,000.

Treadwell Library of the Massachusetts General Hospital, Boston, Mass., U. S. A. Dr. James J. Minot. 7,355.

Library of City Hospital, 878 Harrison avenue, Boston, Mass., U. S. A. Dr. George H. Rowe. 3,605

Library of Tufts College Medical School, 416 Huntington avenue, Boston, Mass., U. S. A. Dr. Robert W. Hastings. 1,800.

Library of the Harvard Medical School, Longwood avenue, Boston, Mass., U. S. A. Miss Ida F. Underhill. 15,000.

BOURNEMOUTH—Library of the Bournemouth Medical Society, Old Christchurch Road, Bournemouth, England. Dr. Frank Belben.

BRIGHTON—Library of the Brighton and Sussex Medico-Chirurgical Society, Brighthelmstone Dispensary, Queen's Road, Brighton, Eng. Mr. Brill. 4,000.

BRISTOL—Bristol Medical Library, University College, Bristol, Eng. Mr. C. King Rudge. 21,000.

BROOKLYN—Library of the Medical Society of the County of Kings, 1313 Bedford avenue, Brooklyn, N. Y., U. S. A. Mr. Alfred T. Huntington. 65,000.

BRUNSWICK—Library of the Medical School of Maine, Brunswick, Maine, U. S. A. Mr. George T. Little 5,005.

BRUSSELS—Library of the Academy of Medicine of Belgium, Palais des Academies, Brussels, Belgium. Mr. Henry Beckers. 100,000.

BUDAPEST—Library of the Royal Society of Physicians of Budapest, VII. Sventkiralyi-utcza. 21, Budapest, Hungary. Dr. Rudolphe Temesvary. 20,528.

BUFFALO—Medical Library of the University of Buffalo, 24 High street, Buffalo, N. Y., U. S. A. Dr. Irving P. Lyon. 8,650.

BURLINGTON—Library of the College of Medicine, University of Vermont, Burlington, Vt, U. S. A. Dr. H. C. Tinkham. 3,000.

CALCUTTA—Library of the Medical College of Bengal. Colutolah street, Calcutta, India. Rakhal Das Ghose. 50,000.

CAMBRIDGE—The Library, New Medical Schools. Downing street, Cambridge, England. Mr. Charles F. Wolfe. 5,500.

CANTERBURY—Library of the East Kent and Canterbury Medical Society, Canterbury, England. Dr. Harold Wacher. 2,000.

CHELTENHAM—Cheltenham Medical Library, Clarence street, Cheltenham, England. Dr. J. Rupert Collins. 2,300.

CHICAGO—Department of Medical Sciences of John Crerar Library, 87 Wabash avenue, Chicago, Ill., U. S. A. Dr. A. C. Girard. 50,000.

Northwestern University Medical School Library, 2431 Dearborn street, Chicago, Ill., U. S. A. Dr. Walter H. Buhlig. 5,020.

Quine Library, College of Physicians and Surgeons, University of Illinois, Congress and Honore streets, Chicago, Ill., U. S. A. Miss Metta M. Loomis. 12,512.

Library of Rush Medical College, University of Chicago, Chicago, Ill., U. S. A. Miss C A. MacCauliff. 17,840.

CINCINNATI—Cincinnati Hospital Library, Cincinnati, Ohio, U. S. A. Dr. E. W. Mitchell. 18,000.

Library of the Academy of Medicine of Cincinnati, 25 East Eighth street, Cincinnati, Ohio, U. S. A. Dr. Arch I. Carson. 3,000.

CLEVELAND—Library of the Medical Library Association, 2318 Prospect avenue, Cleveland, Ohio, U. S. A. Mrs. S. M. Harding. 14,000.

COLORADO SPRINGS—Library of the El Paso County Medical Society, Coburn Library, Colorado Springs, Col., U. S. A. Dr. L. G. Brown. 2,800.

COPENHAGEN—Library of the Copenhagen Medical Society, Kongens Nytorv, 6, Copenhagen, Denmark. Dr. Joergen Moeller. 6,500.

Library of the Ear and Throat Clinic, Kommunehospitalet, Copenhagen, Denmark. Dr. Blegvad. 2,500.

Library of the General Hospital, Kommunehospitalet, Copenhagen, Denmark. Dr. Joergen Moeller. 4,500.

DENVER—Library of the Denver Academy of Medicine, 1434 Glenarm street, Denver, Col., U. S. A. Dr. F. W. Kenney. 3,200.

DUBLIN—Library of the Royal College of Physicians of Ireland, 6 Kildare street, Dublin, Ireland. Mr. Robert Phelps. 16,000.

EDINBURGH—Library of the Royal College of Physicians of Edinburgh, 9 Queen street, Edinburgh, Scotland. Dr. D. Berry Hart. 80,000.

Library of the Royal College of Surgeons, Edinburgh, Nicholson street, Edinburgh, Scotland. Dr. Alexis Thompson. 15,000.

Library of the Royal Medical Society, Melbourne Place, Edinburgh, Scotland. Mr. A P. Ormiston. 30,000.

FALL RIVER—Library of the Fall River Medical Society, South Main street, Fall River, Mass., U. S. A. Dr. George L. Richards. 850.

FLORENCE—Medical Library of the Scientific School, 33 Alfani street, Florence, Italy. Luigi Nobile-Lojacono. 30,000.

FRANKFORT—Senckenberg Library, Viktoria Allee 9, Frankfurt a Main, Germany. Dr. G. Wahl. 70,000.

GALVESTON—Library of the Medical Department of the University of Texas, Galveston, Texas, U. S. A Miss Addie Hill. 7,010.

GLASGOW—Library of the College of Physicians and Surgeons of Glasgow, Faculty Hall, 242 St Vincent street, Glasgow, Scotland. Mr. Alexander Duncan. 50,000.

HARTFORD—Library of the Hartford Medical Society, Hunt Memorial Building, 38 Prospect street, Hartford, Conn., U. S. A. Dr. Walter R. Steiner 4,000

HASTINGS—Library of the East Sussex Medico-Chirurgical Society, 10 Silchester Road, Hastings, England. Dr. Hubert Stanley 3,000.

HAVANA—Library of the School of Medicine of the National University, General Wood Laboratories, Havana, Cuba. Prof. José A Valdés Anciano. 4,800.

JACKSONVILLE—Library of the Morgan County Medical Society, Public Library Building, Jacksonville, Ill., U. S. A. Dr. Carl E. Black. 2,500.

JERSEY—Library of the Jersey Medical Society, 37 David

Place, St. Hilier, Jersey, England. Dr. Charles A. Bois. 350.

KINGSTON—Queen's Medical Library, Kingston, Ontario, Canada. Dr. A. R. B. Williamson. 1,500.

KYOTO—Medical Library of the Imperial University, University Compounds, Kyoto, Japan. Dr. Bunjiro Shima. 25,016.

LEEDS—Library of the Leeds and West Riding Medico-Chirurgical Society, Cookridge street, Leeds, England. Mr. John Merriman. 7,500.

LEICESTER—Library of the Leicester Medical Society, 3 Granby street, Leicester, England. Mr. F. S. Herne. 5,000.

LINCOLN—Library of the Nebraska State Medical Association, Library of the University of Nebraska, Lincoln, Neb., U. S. A. Dr. H. Winnett Orr. 2,500.

LIVERPOOL—Library of the Liverpool Medical Institution, Liverpool, England. Mr. William Jones. 12,000.

LONDON—Library of the Royal Society of Medicine, 20 Hanover Square, London W., England. Mr. Charles Richard Hewitt. 70,000.

Library of the Medical Society of London, 11 Chandos street, Cavendish Square, London, W., England. Mr. George Bethell. 25,000.

Library of the Royal College of Surgeons of England. Lincoln's Inn Fields, London, W. C., England. Mr. Victor G. Plarr. 60,000.

Library of the Royal College of Physicians of London. Pall Mall East, London, S. W., England. Dr. J. F. Payne. 25,000.

Library of the British Medical Association, 429 Strand, London, England. Mr. Spencer Honeyman. 20,000.

Library of the London School of Medicine for Women, 8 Hunter street, Brunswick Square, London, W. C., Eng. Dr. Winifred C. Cullis. 1,600.

Library of the Medicine School of Charing Cross Hospital, 62 Chandos street, Strand, London, W. C., England. Mr. J. Francis Pink. 5,000.

Willis Library, Guy's Hospital, St. Thomas's street, London, S. E., England. Mr. P. Mills. 7,000.

Library of the London Hospital Medical College, Turner street, Mile End, London E., England. Mr. W. Chance. 7,500.

Library of St. Bartholomew's Hospital College, West Smithfield, London, E. C., England. Mr. Alfred Coughtrey. 14,000.

Library of St. Thomas's Hospital, Lambeth Palace Road, London, England. Mr. George Rendle. 3,000.

Library of the University College Hospital, University St., Gower street, London, W. C., England. Mr. L. Rhys Thomas. 8,000.

Library of the Westminster Hospital Medical School, Caxton street, Westminster, London, S. W., England. Mr. W. Fryer. 2,500.

Library of the Medico-Psychological Association of Great Britain and Ireland, 11 Chandos street, Cavendish Square, London, W., England. Mr. George Bethell. 2,000.

Library of the Ophthalmological Society of the United Kingdom, 11 Chandos street, Cavendish Square, London, W., England. Mr. George Bethell. 3,500.

LOS ANGELES—Barlow Medical Library, 742 Buena Vista street, Los Angeles, Cal., U. S. A. Miss Jessie A. Wier. 3,255.

LOUISVILLE—Jefferson County Medical Library, room 700 Atherton Building, Louisville, Ken., U. S. A. Mr. H. S. Smith. 3,000.

MADRAS—Library of the Madras Medical College, Park Town, Madras, India. B. Streenivasulu. 4,997.

MANCHESTER—Library of the Manchester Royal Infirmary, Manchester, England. Dr. F. E. Tylecote. 6,200.

Library of the Manchester Medical Society, University of Manchester, Manchester, England. Dr. Cuthbert E. A. Clayton. 39,012.

Radford Library, St. Mary's Hospital (Whitworth Street Branch), Oxford street, Manchester, England. Dr. D. Lloyd Roberts. 3,350.

MANILA—Library of the Bureau of Science, 153 Calle Herren, Manila, Philippine Islands. Miss Mary Polk. 17,500.

MELBOURNE—Medical Library of the University of Melbourne, Melbourne, Australia. Mr. F. Gladish. 6,000.

MILFORD—Library of the Thurber Medical Association, Milford, Mass., U. S. A. Dr. J. M. French. 200.

MILWAUKEE—Library of the Milwaukee Medical Society, Goldsmith Building, Wisconsin street, Milwaukee, Wis., U. S. A. Dr. J. D. Madison. 5,550.

MINNEAPOLIS—Library of the Hennepin County Medical Society, City Hall, Minneapolis, Minn., U. S. A. Mrs. Carrie C. Jones. 4,407.

MONTREAL—McGill Medical Library, Montreal, Canada. Miss M. R. Charlton. 30,000.

MUNICH—Library of the Munich Medical Society, Althermereck 20, Munich, Germany. Dr. B. Spatz. 22,935.

NEWARK—Library of the Medical Library Association, Public Library Building, Newark, N. J., U. S. A. Mr. John Cotton Dana. 479.

NEW HAVEN—Library of the New Haven Medical Association, 962 Chapel street, New Haven, Conn., U. S. A. Dr. Gustavus Eliot. 5,000.

NEW ORLEANS—Library of the Medical Department of Tulane University, Canal street, between Robertson and Villere streets, New Orleans, Louisiana, U. S. A. Miss Jane Grey Rogers. 4,815.

Library of the Orleans Parish Medical Society, 141 Elk Place, New Orleans, La., U. S. A. Dr. Homer Dupuy. 10,000.

NEW YORK—Library of the New York Academy of Medicine, 17 West 43d street, New York, N. Y., U. S. A. Mr. John S. Brownne. 87,000.

Library of the College of Physicians and Surgeons, Columbia University, 437 West 59th street, New York, N. Y., U. S. A. Mr. G. S. Evans. 1,400.

Library of the Rockefeller Institute for Medical Research, 66th street and Avenue A, New York, N. Y., U. S. A. Miss A. E. Schiedt. 5,000.

NOTTINGHAM—Library of the Nottingham Medico-Chirurgical Society, The Dispensary, Broad street, Nottingham, England. Dr. S. E. Gill. 1,000.

ORANGE—William Pierson Memorial Library, Free Library Building, corner of Main street and Essex avenue, Orange, N. J., U. S. A. Dr. Palmer Potter. 2,403.

PARIS—Library of the Paris Academy of Medicine, 16 Rue Bonaparte, Paris, France. Dr. Laloy. 100,000.

Library of the Faculty of Medicine of Paris, 12 Rue de l'Ecole de Medecine, Paris, France. Dr. Louis Hahn. 200,000.

Library of the Surgical Society, 12 Rue de Seine, Paris, France. Dr. Lucien Hahn. 20,000.

Library of the School of Military Sanitary Service (Val de Grace), 277 Rue Saint Jacques, Paris, France. Dr. Sudre. 23,000.

Public Assistance Central Library of Internes, 3 Avenue Victoria, Paris, France. Andre Mesureur. 35,000.

Library of the Medical and Bacteriological Department of the Pasteur Institute, 25 Rue Dutot, Paris, France. Victor Roussel. 30,000.

Library of the Department of Biological Chemistry, Pasteur Institute, 25 Rue Dutot, Paris, France. Paul Jeantet. 10,000.

Henri Foulard Library, Hôpital Saint Louis, 40 Rue Bichat, Paris, France. Dr. Louis Wickham. 20,000.

Library of the Saltpétrière Hôpital, 47 Boulevard de l'Hôpital, Paris, France. Dr. Lhermitte. 8,000.

Library of the Policlinic of Henri Rothschild, 199 Rue Macardet, Paris, France. Ch. Mettling. 10,000.

PHILADELPHIA—Library of the College of Physicians, southeast corner of 22d and Ludlow streets, Philadelphia, Penn., U. S. A. Mr. Charles Perry Fisher, 86,718.

Medical Library of the Pennsylvania Hospital, Eighth and Spruce streets, Philadelphia, Pa., U. S. A. Mr. Milton M. Bergey. 15,000.

Library of the Woman's Medical College of Pennsylvania. Philadelphia, Pa., U. S. A. Miss Henrietta Newburger. 1,500.

Library of Jefferson Medical College, 10th and Walnut streets, Philadelphia, Pa., U. S. A. Mr. Charles Frankenberger. 4,200.

Library of Hahnemann Medical College, Broad street above Race street, Philadelphia, Pa., U. S. A. Dr. T. L. Bradford. 15,000.

PITTSBURG—Library of the Pittsburg Academy of Medicine, 43 Federal street, Pittsburg, Pa., U. S. A. Dr. Sidney A. Chalfant. 4,500.

PLYMOUTH—Library of the Plymouth Medical Society, Athenæum Chambers, Plymouth, England. Dr. A. Bertram Soltau. 1,650.

POUGHKEEPSIE—Library of the Medical Society of the County of Dutchess, Poughkeepsie, N. Y., U. S. A. Dr. A. L. Peckham. 1,900.

PROVIDENCE—Library of the Rhode Island Medical Society, Public Library Building, Washington and Greene streets, Providence, R. I., U. S. A. Dr. George D. Hersey. 23,500.

PUEBLO—Library of the Pueblo County Medical Society, McClelland Library, Pueblo, Col., U. S. A. Dr. W. W. Bulette. 2,755.

QUINCY—Library of the Quincy Medical Library Association, 4th and Main streets, Quincy, Ill., U. S. A. Dr. E. Zimmermann. 1,256.

READING—Library of the Berks County Medical Society, 540 Walnut street, Reading, Pa., U. S. A. Dr. Frank G. Runyon. 850.

RICHMOND—Library of the Medical College of Virginia, Richmond, Va., U. S. A. Dr. St. George T. Grinnan. 3,000.

ST. LOUIS—St. Louis Medical Library, 3525 Pine street, St. Louis, Mo., U. S. A. Dr. Frank J. Lutz. 11,810.

ST. PAUL—Library of the Ramsey County Medical Society, 260 Lowry Arcade, St. Paul, Minn., U. S. A. Miss E. M. Macquistan. 6,000.

ST. PETERSBURG—Library of the Imperial Academy of Medicine, Hospital Building, St. Petersburg, Russia. Prof. Skoricenko. 170,000.

SAN FRANCISCO—Lane Medical Library, Cooper Medical College, Sacramento and Webster streets, San Francisco, Cal., U. S. A. Dr. Emmet Rixford. 25,000.

SHEFFIELD—Library of the Sheffield Medico-Chirurgical Society, The University, Sheffield, England. Dr. Duncan Burgess. 3,556.

STOCKHOLM—Library of the Caroline Institute, Stockholm, Sweden. Emil Haverman. 40,000.

Library of the Association of Swedish Physicians, Stockholm, Sweden. Dr. E. O. Hultgren. 21,000.

SYRACUSE—Library of the College of Medicine, Syracuse University, 309 Orange street, Syracuse, N. Y., U. S. A. Dr. Frank W. Marlow. 8,000.

TERRE HAUTE—Library of the Vigo County Medical Society, Emeline Fairbanks Memorial Library, Terre Haute, Ind. U. S. A. Mrs. Sallie C. Hughes. 700.

TOPEKA—Stormont Medical Library, State House, Topeka, Kan., U. S. A. Mr. James L. King. 3,460.

TORONTO—Library of the Academy of Medicine, 9 Queen's Park, Toronto, Canada. Miss Mary Scott Watson. 6,000.

TORQUAY—Library of the Torquay Medical Society. Torbay Hospital, Torquay, England. 500.

UPSALA—Library of the Medical Society at the Royal University, Upsala, Sweden. Gustafadde, 7,000.

VANCOUVER—Library of the Vancouver Medical Association, rooms 22 and 23, 633 Hastings street, W. Vancouver, British Columbia. Dr. E. D. Carder. 1,500.

VIENNA—Library of the Medical Society of Vienna. Rotenturmstrasse 19, Vienna I, Austria. Dr. Leopold Senfelder. 2,000.

Library of the Physicians' Association of Vienna, 8 Frankgassestrasse, Vienna IX., Austria. Dr. L. Unger. 45,000.

WASHINGTON—Library of the Surgeon General's Office, 7th and B streets, S. W., Washington, District of Columbia, U. S. A. Dr. Walter D. McCaw. 165,342.

Library of the U. S. Naval Medical School, 24th and E streets, Washington, D. C., U. S. A. Mr. S. W. French. 16,000.

Library of the Bureau of the U. S. Public Health and Marine Hospital Service, Washington, D. C., U. S. A. Mr. J. W. Trask. 3,400.

WAVERLEY—Medical Library of McLean Hospital, Waverley, Mass., U. S. A. Miss E. Kathleen Jones. 4,600.

WILKES-BARRE—Library of the Luzerne County Medical Society, Anthracite Building, Wilkes-Barre, Pa., U. S. A. Dr. Lewis H. Taylor. 4,631.

WINNIPEG—Library of the College of Physicians and Surgeons of Manitoba, 220 McDermott street, Winnipeg, Manitoba, Canada. Miss O. Stewart. 1,500.

WORCESTER—Worcester District Medical Library, 18 Elm street, Worcester, Mass., U. S. A. Dr. Merrick Lincoln. 9,335.

YORK, ENGLAND—Library of the York Medical Society, 1 Low Ousegate, York, Eng. Dr. A. B. Northcote. 5,000.

YORK, U. S. A.—Library of the York County Medical Society, Court House, E. Market street, York, Pa., U. S. A. Dr. Israel H. Betz. 3,000.

Fracture of the Patella.—J. B. Cutter reports a case of fracture of the patella in which the patient refused treatment. About three weeks later he returned to the hospital to obtain a certificate of discharge, having used his leg constantly during the interim, no attempt at treatment or immobilization having been made. There was ligamentous union apparently, the separation of the fragments being three-quarters of an inch. The functional result was remarkably good, there being almost complete extension and no inconvenience in walking.—*Journal of the American Medical Association.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

RATIONAL IMMUNIZATIONS IN THE TREATMENT OF PULMONARY TUBERCULOSIS AND OTHER DISEASES. By E. C. HORT, B.A., B.Sc., M.R.C.P. 4to, 75 pages; cloth; illustrated. Wm. Wood & Co., New York.

DIE ERKENNUNG DES SCHWACHSINNS IM KINDESALTER. Von. Prof. Dr. Th. ZIEHEN. 8vo, 32 pages; paper. S. Karger, Berlin, Germany.

HÄMODYNAMISCHE STUDIEN. Von Dr. med. JOHANN PLESCH. 4to, 240 pages; paper; illustrated. August Hirschwald, Berlin, Germany.

ERHOLUNGS UND KURORTE NACH IHREN HÖHENLAGEN. Von LASIRIFA. 12mo, 66 pages; paper. August Hirschwald, Berlin, Germany.

SYMPTOMS AND THEIR INTERPRETATIONS. By JAMES MCKENZIE, M.D., M.R.C.P. 8vo, 297 pages; cloth; illustrated. Shaw & Sons, London, England.

VERHANDLUNGEN DER VEREINS DEUTSCHER LARYNGOLOGEN, 1909. Herausgegeben im Auftrage des Vereins vom Schriftführer, Dr. med. FELIX BLUMENFELD. 8vo; paper; 246 pages. Price 5 marks. Curt Kabitzsch (A. Stuber's Verlag), Würzburg.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR NURSES. By DIANA CLIFFORD KIMBER. 8vo; cloth; 438 pages; illustrated; $2.50 net. The Macmillan Co., New York.

HOUSEHOLD PESTS AND HOUSEHOLD REMEDIES. By W. R. BOELTER. 8vo; cloth; price 2/6 net; 172 pages; illustrated. John Bale, Sons & Danielsson, Ltd., London, England.

FÜNFZIG JAHRE LARYNGOLOGISCHER ARBEIT AUF DEM GEBIETE DER KEHLKOPFTUBERKULOSE. Von Dr. R. IMHOFER. 8vo; paper; 102 pages; 2.40 M. Carl Marhold, Halle, Germany.

BLINDHEIT UND BLINDENWESEN. Von Augenarzt Dr. Med. HÜBNER. 8vo; paper; 36 pages; 1.20 M. Carl Marhold, Halle, Germany.

TEXT-BOOK OF PHYSIOLOGICAL CHEMISTRY, for Students of Medicine. By JOHN H. LONG, M.S., Sc.D. 8vo, cloth; 306 pages; illustrated; $2.50 net. P. Blakiston's Son & Co., Philadelphia, Pa.

NÄHRUNGSMITTELTABELLE ZUR AUFSTELLUNG UND BERECHNUNG VON DIÄTVERORDNUNGEN. Von Dr. HERMAN SCHALL und Dr. AUGUST HEISLER. 8vo; paper; 42 pages. Curt Kabitzsch, Würzburg, Germany.

OPERATIVE SURGERY, Vol. I. SIR FREDERICK TREVES, Bart., G.C.V.O., C.B., LL.D., F.R.C.S., and JONATHAN HUTCHINSON, F.R.C.S. 8vo; cloth; 775 pages; illustrated. Lea & Febiger, New York.

Book Reviews.

The Thirteenth Greatest of Centuries. By James J. Walsh, M.D., Ph.D., LL.D.; Dean and Professor of the History of Medicine and of Nervous Diseases at Fordham University School of Medicine; Professor of Physiological Psychology at Cathedral College, New York; Life Member of the New York Historical Society; Member of the National Geographic Society; Fellow of the New York Academy of Medicine, etc. Second Edition. With Emendations and an Appendix. Cloth, pp. v-458. New York: Catholic Summer School Press, 1909.

Inasmuch as this book is a digest of Summer School lectures, all explanatory notes and marginal references were rigorously excluded from the first edition. In this second edition, however, it seemed advisable to adduce some authoritative opinions in support of many seeming paradoxes of statement. Accordingly, two appendixes have been added, the first containing so-called history of the period, covering rules and events; the second citing criticisms, comments, and documents. The author has read widely and deeply, and seems to have a happy faculty of putting his finger on the fact or illustration needed for his purpose. In writing a work of this kind there is no question of the immense amount of detail which must be examined and weeded out; and Dr. Walsh has done well in marshalling the data of his subject so as to make a harmonious whole, as well as in the clearness and keenness of his logic. Scholarly contributions to other subjects than medicine written by physicians are rare enough, and we are glad to see that popular opinion of this work has justified a second edition.

Bier's Hyperemic Treatment in Surgery, Medicine, and the Specialties. A Manual of Its Practical Application. By Willy Meyer, M.D., Professor of Surgery at the New York Post-Graduate Medical School and Hospital; Attending Surgeon to the German Hospital; Consulting Surgeon to the New York Skin and Cancer Hospital, and to the New York Infirmary, and Prof. Dr. Victor Schmieden, Assistant to Prof. Bier, University of Berlin, Germany. Second Revised Edition, Enlarged. Illustrated. Philadelphia and London: W. B. Saunders Company, 1909.

That a second revised edition of this work has appeared so soon after the first seemingly shows that many share the enthusiasm of the authors regarding this method of treatment. Although we read in the preface that the "physician who has given the treatment a fair and careful test, no matter in what specialty, and has thus had an opportunity of observing the often remarkable successes that can be obtained, will be so much pleased that he will be eager to give the method a permanent place in his therapeutic armamentarium," we believe few, even of those easily carried away by novelties, will accept without trial the assertion that Bier's treatment is useful in abscesses, arthritis, scoliosis, flat-foot, frost-bite, seasickness, fractures, gonorrhea, headache, dysmenorrhea, cancer, burns, pulmonary tuberculosis, diphtheria, meningitis, and certain diseases of the skin, the eye, ear, nose, throat, and nerves. Making allowances for the author's enthusiasm and for the unconscious exaggeration of the partisan of any method, one can find much of value here, and if he wishes to test for himself the therapeutic efficacy of artificial hyperemia he will find all needed instruction within the covers of this book.

Exercise in Education and Medicine. By R. Tait McKenzie, B.A., M.D.; Professor of Physical Education and Director of the Department, University of Pennsylvania; Fellow of the College of Physicians of Philadelphia and of the American Academy of Physical Education in Colleges; Sometime Lecturer in Anatomy and Medical Director of Physical Training at McGill University; Lecturer in Artistic Anatomy, Montreal Art Association, Harvard Summer School, and Olympic Lecture Course, St. Louis, 1904. With 346 illustrations. Philadelphia and London: W. B. Saunders Company, 1909.

If the author had been content to cover less ground his book on the "cinderella of the therapeutic family" would be much more valuable. Divided into two parts, exercise in education and exercise in medicine, the book starts out most entertainingly with a chapter that presages great things, but almost every chapter thereafter leaves an impression of dissatisfaction. There is too much extraneous matter and too little of the instruction that should be there. Why insert illustrations of "East Side street in New York," of "city conditions showing need of playgrounds in Philadelphia," or of "people throwing flowers to American Turners" in Frankfurt? There is too much historical in the German and Swedish systems of exercise and too little practical. The chapters on physical education of the blind, of the deaf, and of the mentally defective are most valuable and instructive, and the author is naturally at home in the chapter on athletics in college and university, and makes one wish to hear more on the subject, but there is a certain positiveness in his teaching on static deformities of which only an enthusiast would be capable. Possibly he is a trifle sanguine also in the treatment of hernia. "One man played football for years with an enormous scrotal hernia, which he did not even support. He then went to Cuba, did a great deal of horseback riding and other violent exercise, during which it disappeared, is now quite sound, with no return for five years."

Die Erkrankungen der Schilddrüse, Myxödem, und Kretinismus. Von Dr. C. A. Ewald, Prof. ordin. honor. an der Friedrich-Wilhelms-Universität, dirigierendem Arzt am Augusta-Hospital zu Berlin; LL.D. Univers. of Maryland. Zweite, völlig neu bearbeitete Auflage. Mit 26 Abbildungen und einer Karte. Wien und Leipzig: Alfred Hölder, 1909.

The second edition of this monograph on the diseases of the thyroid gland exclusive of Graves' disease has been considerably amplified and largely rewritten. The entire subject of the significance of the parathyroids, for which the author prefers the designation "epithelial bodies," is of recent development, and now finds fairly full discussion, though the work of American observers, particularly in regard to the relation of these structures to calcium metabolism, does not receive very extensive consideration (v. p. 227). The classification of the forms of goiter and of cretinism is interesting: two forms of goiter are recognized, the endemic occurring in definite localities as the result of a water-borne infection, and the sporadic, of noninfectious origin. Cretinism also may be endemic or sporadic; in the former case it is seen in the goitrous districts, is associated with disease, but not necessarily total destruction, of the thyroid gland, and is an infectious disease whose causative agent is still unknown. Sporadic cretinism or congenital myxedema is due to a congenital abnormality of the gland, while juvenile myxedema is an acquired disease, as is the myxedema of adults. Operative myxedema naturally is of definite etiology. For uncomplicated goiters Ewald recommends surgical measures only when internal treatment—chiefly with iodine—has been found ineffectual. The treatise is of much interest and value, and its usefulness is greatly enhanced by a very extensive bibliography.

Angina Pectoris. Part III of Clinical Treatises on the Symptomatology and Diagnosis of Disorders of Respiration and Circulation. By Prof. Edmund von Neusser, M.D.; Professor of the Second Medical Clinic, Vienna; Associate Editor Nothnagel's Practice of Medicine. Authorized English Translation. By Andrew McFarlane, M.D.; Professor of Medical Jurisprudence and Physical Diagnosis, Albany Medical College; Attending Physician to St. Peter's and Child's Hospital and Albany Hospital for Incurables. New York: E. B. Treat & Company, 1909.

This is a short monograph treating very closely of stenocardia in all its aspects—etiology, diagnosis, and treatment, the latter chapter, as one might expect, being the shortest in the book. Neusser favors the nerve theory of angina nectoris, regarding the vascular theory as unsatisfactory and capable of explaining the occurrence of only a small proportion of the paroxysms. The translation is in general well made, but it would have been better to translate the names of drugs, for natrium iodatum, natrium nitrosum, rhodannatrium, and other similar terms are unpleasant to meet and will not be translatable by all readers.

Obstetrics. Vol. 5 of the Practical Medicine Series. Edited by Joseph B. DeLee, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School, with the Collaboration of Herbert M. Stowe, M.D. Series, 1909. Chicago: The Year Book Publishers.

The efforts to lower the material mortality, and yet improve the chances of the child, are to a great extent responsible for the operative trend of obstetrics. The literature of the foreign clinics has furnished us with a large number of valuable statistics as to the indications and relative values of premature labor, version, pubiotomy, vaginal cesarean section and the different varieties of abdominal cesarean section. Good results have been reported in the treatment of placenta prævia by cesarean section. In the absence of fever and complications, early rising in the puerperium has been encouraged in a number of the foreign clinics, and from the reports of a large number of cases the results have been very satisfactory. The book is instructive and interesting.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-first Annual Congress, Held at the Harvard Medical School, Boston, Mass., May 31, June 1 and 2, 1909.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. A. COOLIDGE, JR., OF BOSTON, IN THE CHAIR.

Monday, May 31—First Day.

President's Address.—Dr. A. COOLIDGE, JR., of Boston delivered this address. He spoke of the new Harvard buildings in one of which the congress had assembled, as a noble gift given in trust for the benefit of the profession as a whole. He spoke of the great number of new instruments devised for work in laryngology and rhinology and said that enthusiasm sometimes carried the profession beyond the proper limits. Allusion was made to the recent death of Dr. F. I. Knight of Boston, a founder of the association, and one of the earliest and most successful teachers in America in this department. Information was given with reference to the courses of instruction in laryngology in the Harvard school, there being eight instructors engaged in the work. Dr. Coolidge thought that in connection with the more formal exercises of medical meetings much good might follow informal discussion in small groups and the explanation of favorite theories. It was recommended that the de Roaldes prize to be established by the association should take the form of a medal. Attention was called also to the work of the committee on nomenclature.

Nerve Distribution in Relation to Nerve Disturbances Simulating Local Inflammation.—Dr. A. A. BLISS of Philadelphia spoke of the complicated distribution of the nerves throughout the region of interest to the rhinologist. Pain in this region was not always due to occlusion or retained secretions. It might come from many sources and be reflected to some special area within the nasal territory. The onset of an acute rhinitis would develop a vicious circle, for sensory filaments of the ophthalmic and superior maxillary nerves reacted on the sympathetic plexuses and we had vasomotor irregularities which in themselves increased the irritability of the sensory nerves. In the majority of such attacks there was no exudation in the sinuses, but the pain there was due to involvement in some way of branches of the fifth pair. A safe guide for surgical intervention was the temperature range, duration, and continuance of pressure symptoms, and the mental state of the patient. The removal of impacted cerumen often cleared up a persistent cough. Often patients with supposed mastoid disease were operated on and no disease was found. Under such conditions we should always consider carefully the distribution of painful areas, and we were thus often brought to a discovery of some local cause which was causing a neuralgia and nothing more. Similarly was explained the so-called nasal cough. In some patients any irritation of the nasopalatine nerve, especially opposite the posterior half of the middle turbinate body, would develop this reflex coughing. Cough medicines in these cases were useless. Elongated uvulæ might cause cough by flapping against the pharyngeal walls. The same principles applied to laryngeal areas. In supposed nasal sinus cases transillumination and the *x*-ray were useful in aiding us to arrive at an accurate diagnosis, but they were far from being infallible guides. With all our modern mechanical aids we must depend largely on personal and direct observation, aided by clinical experience. Aggressive operators might be led astray by their surgical zeal and the apparent though not real reason for its exercise. Thus much unnecessary suffering might be inflicted by undue surgical intervention, the evil results of which might not be revealed to anyone unless to the conscience of the operator.

Dr. O. T. FREER of Chicago, said that there was a peculiar reflected pain in antral suppuration. It might often cause supraorbital pain when the frontal sinus was intact. Antral inflammation did not always cause a rise of temperature. Very trivial intranasal catarrhs might cause obstinate coughs. In America we said "sinusitis"; the German said "sinuitis." Which is correct?

Dr. W. L. BALLENGER of Chicago said that in a personal communication from Dr. Duane of New York the latter had informed him that sinuitis was the more correct, though the word sinusitis had been in use so long as to obtain authority as being correct.

Hemophilia, with Remarks on the Hemorrhagic Diathesis.—Dr. THOMAS HUBBARD of Toledo related histories of two cases, one of distinctly hemophilic tendency and the other showing epistaxis due to scorbutus. The first case was operated on for enlarged tonsils and adenoids. Both cases recovered. The author described the various means used to check hemorrhage, including compression forceps, Monsel's solution, adrenalin, calcium lactate per rectum, etc. Bleeding was not from any particular vessel and stitching the pillars together would not have stopped the bleeding. The author then discussed the general nature of the hemophilic diathesis, which he divided into two classes: First, the pathological, or those cases in which there were unaccountable hemorrhages into the skin, mucous membranes, joints, organs, etc., with or without peculiar inflammatory conditions, such as scurvy, purpura hæmorrhagica, and allied affections; and, second, true hemophilia, which was not a pathologic process, but a permanent condition. A differential diagnosis between the two forms was necessary for intelligent treatment. The author then passed on to the treatment of hemorrhage in general, saying that the first indication was to maintain the volume of the circulating medium by normal saline solution. For children small enemata of, say, four ounces were the best method, and such enemata might be given every two hours. If this failed, intracellular injections might be given and in emergencies intravenous injections. Continuous irrigation of the rectum with the saline had been of value. Some authorities advised the injection of fresh human or horse serum. If fresh serum was not available, diphtheria antitoxin had been given, but it was less efficacious. Transfusion of blood was perfectly practicable.

Clinical Experience with Calcium Lactate in Hemorrhages of the Upper Air Tract.—Dr. WILLIAM K. SIMPSON of New York City read this paper. (See p. 505.)

Dr. G. HUDSON MAKUEN of Philadelphia said that he had no fear of hemorrhage in ordinary cases if his patient was under general anesthesia. It was then easy to pass a ligature or suture the pillars. He had used calcium chloride with marked success in nasal hemorrhage.

Dr. GEORGE B. WOOD of Philadelphia said that he had used thyroid extract in cases in which the clotting time of the blood was abnormally long. He now gave it for a short period before all his operations.

Various gentlemen testified to the value of the lactate in their personal experience.

Dr. J. O. ROE of Rochester said that long before the calcium lactate was used he had been in the habit of giving chloride of sodium on the theory of the

lowered specific gravity of the blood. He sutured the pillars in obstinate bleeding after tonsil operations. He had never failed to stop nasal bleeding by packing.

Dr. Emil Mayer of New York called attention to the effects of tags of tissue left after operation as being a cause of bleeding. Postoperative bleeding was not necessarily secondary hemorrhage.

Dr. A. A. Bliss of Philadelphia said that in hospital patients it was very difficult to secure the admission of a hemophilic history. The poorer classes seemed to consider it a disgrace and concealed it. He had lost a case by being thus deceived.

Dr. W. E. Casselberry of Chicago felt that rather too much reliance had been placed on the calcium salts, for he had never observed any effect from the chloride. He had had no experience with the lactate. Most, if not all, hemorrhage about the nose came from some small arterial twig. We should always be prepared with every device necessary to stop arterial hemorrhage.

Dr. H. L. Swain of New Haven said he believed that every hemophiliac had a different kind of blood-vessel from the ordinary person. Consequently mere drugs of any kind were without effect.

Dr. R. C. Myles of New York said that some patients became hemophiliacs to all intents and purposes after they had lost a large amount of blood, but not till then. It was a wise plan to place some thin rubber tissue against bleeding surfaces in the nose and pack against this.

Further Report of a Case of Cancer of the Tongue.—Dr. Robert C. Myles of New York City made a further report on a case already brought before the association in 1907. About two months ago the patient consulted Dr. Myles, complaining of pain and soreness in the operation scar. There was a crater-like ulcer in the center of the cicatrix about 8 mm. in diameter, but after the extraction of an irritating tooth the ulcer healed. In the interval since the first operation two and a half years ago the left side of the tongue had atrophied and shrunk until the base dropped back against the posterior pharyngeal wall, the side being about one-third of an inch farther forward and downward than the other side at the base, while the tip of the same side, which was not removed, shriveled, curled up, and became distorted. The resulting condition had caused the patient much discomfort in speaking and eating. This annoying condition had probably resulted from the removal of longitudinal muscular fibers and by cutting off the nerves and blood-vessels at the base of the tongue. Dr. Myles thought that it would have been better to remove the entire side of the tongue.

Prolonged Styloid Process.—Dr. Charles W. Richardson of Washington, D. C., gave the history of one case and referred to other published cases and reported one case of complete ossification of the stylohyoid ligament and discussed some of the anomalies of this region. His own patient was a woman of twenty-five years of age, who had had for some years irritation referable to the left tonsillar region, from which a long piece of bone had been removed some years previously. A recurrence of symptoms led her to seek further relief and it appeared that just within the anterior tonsillar fold and parallel to its course there was a narrow, slightly movable bony ridge. Under cocaine the anterior fold was opened up its full length and the bony process exposed. The latter was removed by successive bites with bone forceps. Recovery was without incident.

Several of the members related similar cases from their own experience.

Etiology and Treatment of Dentigenous Cysts.—Dr. D. Crosby Greene, Jr., of Boston said that it had been shown that it was possible to make an artificial epithelial cyst by transplanting a bit of skin epithelium with its supporting cutis into the deeper tissues, as into the abdominal cavity. The epithelium, growing in its new location, spreads over the space into which it had been placed, for which it made a lining with a small cavity within. Such an artificial cyst would continue to grow indefinitely. On the currently accepted theory of pathologists in regard to the growth of tumors, the formation of an artificial epithelial tumor within the jawbone could be accounted for rationally. The teeth were essentially epithelial structures, developed by invagination of the jaw epithelium into the body of the jaw. Other elements entered into the final tooth structure, but the origin of the tooth was this ingrowth of the jaw epithelium. Now, doubtless a bit of this ingrowing epithelium was pinched off as an island of isolated epithelial tissue, and such an island pinched off from a tooth root grew in an atypical way, with the resulting formation of a cyst. In order to cure thoroughly such growths every bit of the epithelial lining must be removed, otherwise they might recur. The cavity must be opened widely, curetted thoroughly, and drained completely. This opening might be made into the antrum instead of into the mouth, thus avoiding infection from the latter. The closure of the cavity was often extremely slow, in spite of every attention to surgical technique. The antrum method was especially applicable to large cysts. One case history was given illustrated by an *x*-ray plate.

Dr. W. E. Casselberry asked if there was any method of distinguishing between dentigenous cysts and hydrops antri. He had reported cases under the latter title, but had always felt some doubt as to the correctness of his diagnosis.

Dr. N. H. Pierce of Chicago said that there were two kinds of dental cysts, one due to the inflammation and the other due to errors in development. Cysts arising from inflammation of the peridental mucosa were often removed by the dentist, as the cyst was perched on the end of the root. This might come to occupy the entire antrum and cause what Dr. Casselberry had called hydrops. But this could not cause bulging of the antral wall. This came only from a true dentigenous cyst. The fluid in the latter contained cholesterin crystals.

Dr. J. H. Bryan of Washington believed in the existence of hydrops antri and also that it might arise from true dentigenous cysts. There was also such a thing as the hydrops of the frontal sinus.

Dr. D. Bryson Delavan of New York thought it would be interesting to know what relation, if any, these cysts bore to the expansion found in the ethmoid cells and middle turbinate body.

Dr. Greene said in closing the discussion that it would be possible to distinguish between cyst and hydrops by washing out the cyst by puncture made from the cyst to the mouth under pressure. In cyst you got no fluid from the nose through the bulging in the mouth. If necessary a puncture could be made into the antrum intranasally and then if the puncture did not result in fluid coming from the nose one could see the cavity was not the antrum. Transillumination on the side of a dentigenous cyst always gave a brilliant illumination.

Surgery of the Esophagus.—The afternoon session opened with a symposium on the surgery of the esophagus, the first paper being by Dr. S. J. Mixter of Boston (by invitation), who considered the subject from

the standpoint of the general surgeon. He did not believe that modern instrumentation did away entirely with the general surgeon in reference to esophageal lesions. He detailed his personal experience with esophageal strictures and spoke of the various means of relieving them. In the detection and removal of foreign bodies modern methods with the esophagoscope had scored many brilliant successes, but in the treatment of strictures the older surgical methods still had many advantages.

From the Standpoint of the Laryngologist.—Dr. Chevalier Jackson of Pittsburg continued the symposium, discussing the question from the laryngological point of view. He said that in all cases a body which had entered the air passages could be brought out by the same route and that surgical operations to effect this result were no longer necessary. Rest of the esophagus to reduce the ever-present inflammation was absolutely necessary and only fluids should be allowed. In case of new growths, etc., the patient should have an early gastrostomy and always before a resection of the esophagus the stomach must be emptied of food (it never could be of secretions) and the bowels emptied by enemata. Care must be taken before operation to exclude aneurysm. The blind passage of a sound in a gullet not examined by previous direct vision was a dangerous procedure. The history of stricture from accident did not exclude malignancy. In the author's experience stricture was amenable to treatment by *bonginage per tubam*, dilatation with esophagoscopically placed laminaria tents, esophagoscopic string-cutting dilatation and Abbe's retrograde string-cutting method. These methods were illustrated by the author, who also exhibited various instruments. He also referred to the operations of cervical esophagotomy, lateral cervical esophagotomy, and subhyoid pharyngotomy, gave the indications for each, and gave his experience in five cases, two of inoperable malignancy and three of stricture, in which he had inserted a tube into the stenosed lumen, which enabled the patient to swallow liquids and raw and soft-boiled eggs. He also described the operation of autoplastic repair of the esophagus. He concluded by saying that in no case of dysphagia should esophageal procedure precede esophagoscopy, and it should be used to exclude neoplasms, spasms, compressive and inflammatory stenoses, as well as ulcerations and varicosities. Resection of the upper portion of the esophagus, if it interfered with glottic closure, was so sure to be followed by septic pneumonia that it was wiser to close off the larynx or to extirpate it, bring the trachea forward and stitch it to the skin. In all these operations the strictest watch over the entire operating-room organization is necessary. Nurses and interues were apt to be led into carelessness by the fact that the field of operation could not be sterilized. They forgot that while the patient was more or less immune to the organisms he himself harbored he was not immune to organisms even of identical kinds introduced from other sources.

Esophageal Cases.—Dr. Harris P. Mosher of Boston continued the discussion giving the histories of two cases of stricture of the esophagus with dilatation and one of diverticulum, all resulting successfully. He said that the lumen of the gullet was very much larger than we were accustomed to think, both in the infant and adult. At one year of age it would pass a flat pearl button one inch in diameter. Between two and three years it would admit to its upper part the end of a Jackson spatula. The older text books stated that three-quarters of an inch was the safe limit for dilatation in stricture cases but this measurement was manifestly too small. A negative examination with a small tube under cocaine was useless and amounted to nothing. Ether was advisable. Strictures were best diagnosed and treated by means of the esophagoscope and instruments used through it. Opening of the stomach for nonmalignant strictures ought to become a rare procedure. To open the gullet from the side of the neck for the removal of smooth foreign bodies was already obsolete surgery. The ballooning of the esophagus for locating the lumen of tight strictures bids fair to be a great help to us. The direct method of carrying a capsule filled with thread through the stricture into the stomach was much better than feeding the thread to the patient. Not all strictures could be dilated. Some would have to be cut. The instruments for this were similar in principle to those used in cutting urethral strictures. For perhaps two inches in the upper part of the gullet it was safe to cut backward and risk perforating the posterior wall.

Dr. Emil Mayer of New York opened the discussion and referred to a child with congenital stricture of the esophagus whom he had seen, and whose history had been reported twenty years ago. The passage of a large bougie, under anesthesia, enabled her to swallow. Since that time she had grown up in a perfectly normal way. In a recent case of a man a bougie was arrested nine inches from the teeth and could not be passed further. A diverticulum was thought of, and a piece of rubber tubing was passed and then an *x*-ray picture taken showing a pouch. Dr. Mayer thought it was risky to fill such pouches with bismuth, as it might be difficult to get it out.

Dr. J. O. Roe of Rochester referred to two cases of internal esophagotomy he had reported, the first in this country. In one patient, a boy of eight years, with stricture, he had first passed a small bougie and then the esophageal knife. Five years later the boy was perfectly well. The second patient was a woman of thirty years of age, with stricture following the lodgment of a chicken bone in the throat. Dr. Roe said that he had now under observation a woman of sixty-five years of age with a pouch of the gullet, and that by passing a hollow bougie occasionally he was able to keep his patient in good condition. He did not think it quite safe to do any cutting operation in this case.

Dr. G. L. Richards of Fall River referred to the case of a colleague who had inserted the familiar "coin catcher," found it impossible to remove it and had to do a tracheotomy. He supposed the instrument had been caught by the cartilage, which was not pressed downward and forward, as Dr. Mosher had suggested.

Dr. D. Bryson Delavan of New York thought that the advance of surgery in this country was to-day being seriously threatened by the too general operating in cases requiring special skill by men not specially qualified for it. Such work as that described to-day should be given to those men who make a special study of it, rather than to general surgeons indiscriminately.

Dr. Jackson said that he regarded the old-fashioned "coin catcher" as a dangerous instrument, as it might get caught, tear out the inside of the larynx, and bring the patient into great danger.

Some Observations upon the Complete Extirpation of the Diseased Faucial Tonsil.—Dr. J. S. Gibb of Philadelphia spoke particularly with reference to the method followed with the boys who entered Girard College in his city. General anesthesia was used except with older boys with nonadherent tonsils. The tonsil was pulled from its bed and its attachments to the pillars broken by the Allis blunt dissector. In case the attachment was very firm, scissors or tonsil knives were used. The finger was introduced and an endeavor made to break up the deeper adhesions and leave the tonsil hanging to be removed with

the wire snare. Fragments of tissue remaining could be removed with the punch forceps. If it was necessary to remove a tonsil at all it should be done completely. The wire snare was far more efficient than the tonsillotome in bringing about the desired condition, viz., removal of all diseased crypts. In this method of finger enucleation too strenuous use of the finger should be avoided in breaking up the adhesions. It was far better to snip with a curved scissors. At times the reaction was greater than with the tonsillotome, in spite of all care. Of one hundred cases thus treated the average time in the infirmary was four days. In ninety there was a fever between 99° and 101.5°. In nine cases in which the friable nature of the tonsillar tissue was very pronounced, and in which there was much dissection and the use of punch forceps called for, the fever rose to 102° and over. In two there was regurgitation of fluids through the nose. The fauces were indurated and there was sloughing over the area of the tonsillar wound. It was rare to have any severe bleeding in this method.

Dr. E. L. Shurly of Detroit commended the views of Dr. Gibb, but said that, while we were all familiar with the immediate results of tonsillotomy, we did not know so much about the remote results. We must remember that the tonsil had an internal secretion, and we did not know the possible results on the pharynx, stomach, and contiguous or neighboring organs following the removal of all the tonsillar tissue. He said that disagreeable atrophy might ensue. We should indeed remove all diseased crypts, but have we not done enough by so doing? Should we not leave enough tissue to perform the functions of the tonsils?

Dr. W. E. Casselberry of Chicago did not agree with Dr. Shurly. We should always remove the tonsillar tissue completely. He used sharp cutting instruments in the operation. We should be sure to remove the tissue included within the velum, which he had named the "velar" lobe. He described his method of operating. He used a tonsillotome, which was a modified Mathieu instrument with the fork cut off and had a snarelike action.

Dr. O. T. Freer of Chicago used sharp instruments in freeing the tonsil from its adhesions. He separated the velar lobe last, making traction on the tonsil by means of a sickle-shaped knife. In this way the organ was turned wrong side out and cut away with a curved knife.

The method of finger dissection was commended by several members.

Dr. J. F. Barnhill of Indianapolis said that whatever function the tonsil might have, there was plenty of other tissue in the throat which would take care of that function, especially since the tonsil was diseased. The tonsil pits often filled up after removal with granulation tissue, but sometimes adhesions formed between the anterior and posterior pillars, and these might pile up on the tongue and bind it down. After-pain was less with sharp-cutting instruments. He made firm pressure with a pad soaked in hydrogen peroxide immediately after removal, and then when the pad was thoroughly dry he covered the area with Monsel's solution, but he did not believe in using this solution until the area was fully dry.

Dr. C. G. Coakley of New York said that there had been in his cases anywhere from two to four weeks after operation a small mass of granulation tissue, which he removed by either the punch or nitrate of silver. There was often left an irregularity of the lower edge of the velum on the two sides, and he wondered what effect, if any, followed in professional voice users.

Dr. G. Hudson Makuen of Philadelphia thought that one great element of value in Dr. Gibb's paper was that he had been able to watch his cases so closely and report on their condition some time after operation. He would as soon think of leaving a decayed tooth root in the mouth as to leave a portion of a tonsil.

Dr. R. C. Myles called attention to the basi-lateral tonsils he had described some fifteen years before. He had seen them extending at least three-quarters of an inch into the palate, and when the entire capsule had been removed there had been a cellulitis extending into the zygomatic fossa. Sections of the superior constrictor muscles were too often removed along with the tonsils.

Dr. J. Price-Brown of Toronto had been told by a music teacher of his city that several pupils had had their singing voices practically destroyed by the removal of the tonsils.

Dr. W. K. Simpson of New York thought that we were too apt to base our opinion on the immediate sequel following removal of the tonsils, and that we might get from the filling up of the tonsillar fossa with cicatricial and connective tissue an interference with the muscular action of the velum which would be just as harmful as the leaving behind of a small portion of the tonsil.

Dr. J. O. Roe said that patients sometimes complained more of septic trouble around the neck and of glandular swellings after the tonsil operation than before it. When a tonsil was diseased it was diseased all the way through, for the crypts went all the way to the bottom of the tonsil, and if one left a portion behind one had increased absorption of the septic material in the region.

Dr. Emil Mayer of New York deprecated the use of the finger. Modern surgery called for the use of rubber gloves. He used a blunt dissector with an edge filed so that it could be used as a knife. He thought that too much emphasis had been laid on the amount of blood in these regions.

(To be continued.)

AMERICAN ORTHOPEDIC ASSOCIATION.

Twenty-third Annual Meeting, Held at Hartford, Conn., June 14, 15, and 16, 1909.

The Place of Arthrotomy in Tuberculous Joint Disease.—Dr. V. P. Gibney said that no material advance had been made in the treatment of these joints during the past three or four decades. He thought that orthopedic surgeons should be able to do just as good work as abdominal surgeons, and that exploratory operations in the joint were no more harmful than similar operations in the abdomen. Statistics showed that no one had been able to demonstrate that tuberculous meningitis was a sequel of operative treatment, and modern aseptic surgery should make an arthrotomy perfectly safe. He also stated that there was no better way of disposing of the tuberculous lesion in the joint capsule.

Dr. Griffith wished to know whether any improvement in either the treatment or the length of time required for the cure of these cases had been made in the past three or four decades.

Dr. Gibney did not think that much headway had been made, and said that if any progress was to be made investigations would have to be started on entirely new lines. The joints should be cleaned out. He thought that orthopedic surgeons were too cautious in attempting this, for fear of stiffening the joint up more.

A Case of Myositis Ossificans Associated with Multiple Exostoses.—Dr. Gibney also showed a patient, a girl of eleven years. When six years of age she fell and injured her knee and hip. This seemed to start up a series of exostoses in various parts of the body, occurring at different times. Finally the jaw became locked, so that she could not open her mouth more than a quarter of an inch. In attempting to operate for this he broke off a couple of teeth, but could do nothing else. She could eat better after this, as food could be introduced through the opening. Though

there was slight improvement subsequently, the patient seemed to be getting steadily worse, no form of treatment having had much effect.

Dr. RIDLON said that within the last year he had seen a case in which the ossified condition was very distinct, but which afterward disappeared. He utterly failed to explain the cause of the disappearance.

Dr. W. E. BLODGETT spoke of a similar case, in which ossification had occurred in the biceps muscle after injury, disappearing entirely later.

Dr. GRIFFITH suggested changing the diet and watching the excretions, particularly the urine, as he thought that if the metabolism could be changed there would be a marked improvement in many cases.

Dr. G. G. DAVIS asked whether it were possible that thymus extract could be of benefit in cases of myositis ossificans.

Dr. E. W. RYERSON spoke of the case of Dr. Ridlon and said that the ossification seemed to be in large plaques spread over the shoulders and biceps.

Dr. GOLDTHWAIT said that he had referred to a case of progressive myositis ossificans which Dr. Painter and he had studied together. This case was studied metabolically, without any striking findings. In spite of the dietetic and other treatment, it progressed unfavorably.

Dr. MICHAEL HOKE spoke of a case of multiple exostoses, in which a spur had broken through the skin, ulcerating at the tarsus. He did not think that much good came from removal of the exostoses.

Further Observations Upon the Bismuth Paste Treatment of Tuberculous Sinuses.—Drs. JOHN RIDLON and W. BLANCHARD in this paper said that at the last meeting of the American Orthopedic Association they had reported upon six months' experience in the bismuth paste treatment of tuberculous sinuses. After a year of additional experience they felt better able to present the value, limitations, and dangers of the treatment. Their conclusions were as follows: It invariably failed in cases of marked amyloid degeneration. It failed much more frequently in new sinuses than in those that had existed several months or years. It should never be used when the *x*-ray showed a sequestrum. Its continued use was dangerous when large pus sacs became filled with residuary bismuth. It cured a majority of the cases of old tuberculous sinus. They opened, drained, and injected bismuth paste into tuberculous abscesses to their full capacity; the openings closed while the cavities remained sterile. They had not had a case of bismuth poisoning, but they recognized a danger in filling large abscess cavities.

Dr. GIBNEY referred to a case of sinus of twenty years' standing that he was sure had been cured by bismuth.

Dr. H. A. WILSON said that he had used the bismuth paste for awhile, but that he was afraid of bismuth poisoning, so had substituted for it a preparation made of the identical ingredients minus the bismuth.

Dr. ALBERT FREIBERG believed that a great part of the tuberculous sinuses that existed in joint disease were there because the tuberculosis was still active.

Dr. RYERSON considered that it was dangerous to cut into any uncontaminated tuberculous abscess that was not evidently going to burst. He thought it would be better to treat it conservatively.

Dr. A. G. GILLETTE did not think that there had been sufficient emphasis laid on the danger of the use of early injections. He mentioned a case in which he had opened a tumor and found it filled with bismuth, which had been accumulating from the repeated injections. He thought that the physician should wait a little and see whether the bismuth came out instead of following up the injections.

Dr. EMIL C. BECK explained that cases with no basis of bone in the cavity would clear up at once under influence of the paste. In them, on the third or fourth day, the secretion became serous, and the sinus opening was covered by a scale-like membrane resembling that found on the tonsil in diphtheria. He also said that the bismuth paste must reach every crevice in the sinus or the secretions would remain purulent and the result would be unsuccessful. If the members failed to get good results from this treatment, they must seek for the cause in their technique.

Dr. BLANCHARD said that they did not open old abscesses that were stationary and likely to remain so, but that if they could open and inject abscesses that were going to open spontaneously the majority of them would heal up without any trouble or any infection. The reason for some of the bad results was that cases with retained sequestra had been injected and the fistula closed up, the result being simply a corking up of a broken-down tissue.

Some Myogenous Types of Rigidity of the Spine.—Dr. GEORGE B. ELLIOTT, New York, divided these cases into two classes: (a) Chronic muscular spinal rigidity (rigiditas dorsalis myopathica), and (b) myositis ossificans. He reported a number of cases and presented casts.

Chronic Inflammation of the Lower Epiphysis of the Tibia.—Dr. CHARLES H. JAEGER of New York reported five cases in which limp was the only symptom for which the patients sought advice. Roentgenograms showed a flattening of the head, with a thickening and, in some cases, necrotic areas of the neck and femur. The clinical course of these cases was that of a chronic limp with increasing limitation of action.

Toxic Arthritis of the Hip in Children.—Dr. MICHAEL HOKE gave the details of several cases of hip-joint disease, both in the acute and chronic stage. He said that the physical signs could be stimulated by toxic inflammation of the joint.

Operative Remodeling of the Tarsus for the Immediate Correction of Severe and Relapsed Forms of Clubfoot.—Dr. BERNARD BARTOW of Buffalo explained the remodeling of the deformity of the astragalus, cuboid, and calcaneum, by which the deformed foot is replaced and maintained in an overcorrected position pending adaptive changes in those bones.

Dr. H. L. TAYLOR of New York said that Dr. Myers of New York, quite a number of years ago, had advocated excavation of the astragalus.

Suggestions as to the Improvement of the Plaster of Paris Technique.—Dr. ALBERT H. FREIBERG of Cincinnati said that up to the present time a considerable quantity of plaster has been lost in manipulating plaster-of-Paris bandages. He demonstrated a manner of overcoming this by the use of paper napkins; also an improved method of making removable plaster splints for treating the ankle, elbow, etc.

Dr. JAEGER said that he could testify to the value of Dr. Freiberg's device, which he had tried for a year or more. He, however, had used newspaper to wrap the plaster bandage in, dropping the whole thing into a pail of water, and had found that most of the bandage remained in the paper. He thought the paper napkins an improvement on the newspaper.

Dr. J. K. YOUNG of Philadelphia asked how Dr. Freiberg held the plaster in place while putting on the second circular bandage.

Dr. FREIBERG replied that he held the limb in the position in which he wished to fix it. The plaster was then applied by an assistant, after which he himself wrapped a bandage around the plaster. When the plaster had set the cast was taken off and reapplied, with a lining of cotton, if necessary.

A Preliminary Report of the Use of Animal Membrane in Producing Mobility in Ankylosed Joints.—Dr. W. S. Baer reported to the society eight cases of this procedure.

Dr. Osgood said that he had used some of this membrane, which Dr. Baer had sent to him. At the end of two weeks there was an increase of motion in the knee. There is now 80° of motion in this joint, which is painless. Dr. Osgood said that even if no better result were secured in this case the patient would be better off than before.

Dr. Jaeger had found that the pathological changes that had taken place in muscles that had been contracted for a number of years formed a serious obstacle to the treatment, the muscles having been sometimes board-like in consistency.

Dr. Baer agreed with Dr. Jaeger that the bound-down and atrophic condition of the muscles is a great hindrance to success, and said that massage should be started immediately after the insertion of the membrane, which was inserted in two pieces, one covering the front part of the tibia and going underneath the patellar ligament, and the other being laid between the patella and the top of the superior portion of the condyles.

Tendon Transplantation in Flatfoot.—Dr. E. W. Ryerson of Chicago advocated division of the peroneus longus and brevis in operations for correcting the malposition and said that there was a possibility of transplanting one or both these tendons to the inner border of the foot, thus relieving the distorting tendency, and supplying a partially corrective force.

Treatment of Talipes Valgus.—Dr. R. T. Taylor of Baltimore said that it was his aim to discard plates entirely in this condition, as their use was often abused. He also demonstrated single-brace straps for talipes equinovarus.

Dr. Cook said that anything that held up the inner posterior arch must divert the outer posterior, and when a foot was inverted the outer edge was depressed and the inner edge raised. He also remarked that Dr. Taylor had not done away with plates at all, but had merely built them in his shoes.

Etiology of Hallux Valgus.—Dr. J. K. Young of Philadelphia ascribed the deformity to the presence of a supernumerary bone between the internal cuneiform bone and the base of the first metatarsal. He gave the clinical histories of some cases and exhibited *x*-rays and specimens to verify his hypothesis.

Dr. Freiberg said that Dr. Young's hypothesis had been presented in such an incomplete manner that one would not be justified in drawing conclusions from it.

Dr. John Dane of Boston said that he had found a large number of supernumerary bones in this locality, but that in many of these cases this supernumerary bone had failed to produce hallux valgus.

Dr. Riely said that Dr. Young's *x*-ray had made him realize that he had a patient with the same condition. He had had an *x*-ray taken of his case and had found the supernumerary bone.

Dr. Young, replying to Dr. Freiberg's remarks, said that he hoped that every man in the society would begin to examine the specimens in their possession. As to Dr. Dane, he admitted that not more than one or two out of the several varieties of supernumerary bones produced this deformity; but he was inclined to think that it was his kind that produced this deformity.

A Method of Anchoring Transplanted Tendons.—Dr. S. L. McCurdy of Baltimore said that the operation consisted, where it was possible, in wrapping the tendon entirely around the bone, or passing it through the ligament, and that he preferred to secure it to some dense or firm tissue rather than simply to suture it to the periosteum, thus guaranteeing a firm anchorage after union.

Dr. Rugh said that he had not used iron wire, but had employed wooden screws for making adjustments, particularly of the tibia. He had never had any harm from silver wire, but said that he would try the iron, as it was stronger than silver and could be used in smaller size.

Dr. Wilson thought that if coin silver wire were used it would remove the objection to silver wire because of its much higher strength. Iron-wire nails always produced irritation by corroding, whereas coin silver would not corrode.

Study of Unusual Cases of Caries of the Spine in Adults, with Reference to Early Diagnosis.—Dr. E. G. Brackett said that he intended to include in his paper some of the special features of caries of the spine, and to study them, by classifying them into types and by the grouping of symptoms, with reference to a more accurate diagnosis of the part of the vertebra affected.

Dr. C. L. Starr of Toronto, Can., said that two points had been impressed upon him: First, that by continued hyperextension of these spines the fusion of the bones might be prevented; and second, that if one succeeded in getting fusion of the bones and protection of the spinal canal and its contents this must be done by a prolonged treatment with apparatus, keeping the spine in fixation long enough for the bony processes to take place.

An Operation for Infantile Cerebral Hemiplegia, with Reports of Two Cases.—Dr. John Joseph Nutt of New York had devised this operation to give prolonged rest to the lower neurons, and thereby rest the upper neurons, on the hypothesis that the destruction of cerebral tissue due directly to the original lesion was small in comparison with the total area involved. The rest and repair of certain cells directly produced by the operation should influence indirectly the rest and repair of others.

Dr. Baer said that in cases of anterior poliomyelitis in which he had tried nerve-severing his effort had been to see whether division of the sciatic nerve and the twisting of the nerve on itself would let the neurons spread out and go down the bad paths into the distal portion of the nerve, as well as the good, but that the neuron selected the path it had originally gone down.

Dr. D. R. Fisher of New York said that the condition could be relieved, but not cured. No inflammatory condition remained, but merely an overaction of the cells. By removing this sensory irritation one gave the cortex a chance to rest. For the time being the muscle was paralyzed, and this afforded an opportunity to apply treatment to the opposing muscle, which was weaker than the spastic muscle. He did not believe that a return of mental power could be expected, except in young patients.

Dr. Ryerson said that he had obtained good results by transplanting the hamstrings forward into the patella, the children learning to walk in a year and a half. He did not believe that anything could be done mentally for entirely idiotic patients, but thought that a good deal could be done in other cases.

Dr. Nutt said that the interval between the time of the operation and the return of power had been nine months in one of his cases. Sensation in the small sciatic was entirely paralyzed. A great many cases of diplegia had been reported in which more improvement had been noted than one would expect from sim-

ple tenotomy. The lesion had occurred when his patient was three years old and she was then thirteen, and the nurse had said that she had noticed some mental improvement since the operation.

A Preliminary Study of the Mechanics of the Upright Position, with Especial Reference to Backache (A Combined Orthopedic and Gynecological Study.)—Drs. R. W. Lovett and E. Reynolds of Boston described a method for automatically determining the center of gravity of the individual in the upright position. The relation of the center of gravity to the hip joint, sacro-iliac joints, feet, etc., determined, they contended, the amount and character of back-strain. They had studied and formulated the effect of corsets and high-heeled shoes upon the balance of the body, and upon the position of the center of gravity, and exhibited charts illustrating this.

Dr. Freiberg said that the only questions in his mind were what displacement of the center of gravity meant and whether the proper method had been adopted for correcting what was a pathological condition. He had heard nothing of what had put the center of gravity forward and thought that the logical thing to do would be to go at the cause and correct it. He had not yet recovered sufficiently from his astonishment to swallow with composure the high heels and the corsets that he saw pictured on the walls.

Dr. Sayre agreed with the view that many cases of backache are due to intrauterine and intrapelvic causes, and that many of the pelvic abnormalities come from abnormal positions held on account of deficient muscular force. He thought that the chief use of a corset was to keep the bands of a woman's skirts from cutting into her. He had had difficulty in getting corsets made sufficiently loose over the iliac crests not to be uncomfortable when they were tight enough over the buttocks.

The Relation of Posture to Human Efficiency and the Influence of Poise Upon the Support and Function of the Viscera.—Dr. Joel E. Goldthwait of Boston said that the human body is a delicately balanced organism and that no part can be used with undue strain without straining other parts and wasting energy. In normal balance the muscles and ligaments are used without undue strain, and the movements are made with the minimum expenditure of energy. Correct balance is important because of its effect upon the joints, bones, muscles, and ligaments, and because of the interference with visceral support that must take place when the poise is materially disturbed.

Dr. McKenzie approved of training the physical organism so that it could maintain the ideal attitude, rather than of rectifying postural defects by braces.

Dr. Riely had no doubt that it was the pressure of the muscles that caused the stagnation in the anterior and posterior vertebral columns, but thought that it was obstruction in cases of spine disease by the disease in the bodies of the vertebræ, as the veins that enter the bodies are very large.

Some Notes Concerning Congenital Deformities.—Dr. Augustus Thorndike of Boston gave a short historical sketch of theories of causation, which now seem to have narrowed down to three: heredity, mechanical influence, and maternal impressions. He said that further study was needed to reveal the true etiology and chronology of the inception of skeletal deformities, and that these studies could be made on human embryos, abortion sacs, and the embryos of certain of the lower animals.

Dr. Rugh was not yet convinced that maternal impressions played no part in the production of congenital deformities, and cited recent investigations demonstrating the presence of nerve fibers in the placenta and in the umbilical cord. This, he said, had gone a long way toward establishing the fact of a more intimate nerve relation between the mother and child than had previously been suspected. He felt that in certain cases this acted as a factor in producing congenital deformities.

Dr. McKenzie said that he had lately seen a boy whose right arm had apparently been amputated just above the elbow and who showed other congenital deformities.

Dr. Baer reported an almost identical case in which there was also complete amputation just below the elbow.

Dr. Thorndike said that he had been surprised to find so little about maternal impressions in the literature and that he was inclined to agree with Dr. Rugh regarding them. He hoped that Drs. McKenzie and Baer would report their cases, as he had found the cases of congenital amputation high up so rare.

A Case of Bilateral Congenital Dislocation of the Head of the Radius; and a Preliminary Report of a Case of Congenital Absence of the Acromion Process, Bilateral.—Dr. William G. Turner of Montreal read these two papers. The first case presented a marked increase in the length of the radius as compared with the tibia, nondevelopment of the coronoid fossa, and absence of the orbicular ligament. He exhibited photographs and radiographs of the second case, showing a condition not previously described.

Increased Growth of the Shaft of the Femur Following Fracture.—Dr. John Ridlon of Chicago described two rather unusual cases of this kind in his experience.

Dr. Galloway said that Codivilla had recommended a plan to apply traction directly to the skeleton by driving a spike through the os calcis, thus avoiding the sores that result when pressure is made by plaster dressings to maintain the correction made at the time of operation. He had used Codivillas' method in two cases and had found it of value.

In addition to these, the following papers were read but not discussed:

"A Simple Dressing for the Treatment of Tuberculous Disease of the Shoulder Joint," by Dr. Arthur J. Gillette of St. Paul; "Joint Tuberculosis, with Especial Reference to Its Pathology," by Dr. Leonard W. Ely of New York; "A Further Report of a New Operation for Osteoarthritis and Certain Other Deforming Affections of the Hip," by Dr. Fred H. Albee of New York; "The Ultimate Results in the Treatment of Congenital Dislocation of the Hip," by Dr. E. H. Bradford of Boston; "The Use of Braces in the Treatment of Congenital Luxation of the Hip," by Dr. G. G. Davis of Philadelphia; "Spina Bifida Occulta," by Dr. J. W. Sever of Boston; "Congenital Absence of Vertebræ Below the First Sacral and Malformation of the Lower Cervical and Upper Dorsal Vertebræ," by Dr. Ralph R. Fitch of Rochester. Besides these, a few selected candidates' theses were read, one or two of which were discussed. The other papers on the program were read by title.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Augustus Thorndike of Boston; *First Vice-President*, Dr. Albert H. Freiberg of Cincinnati; *Second Vice-President*, Dr. Michael Hoke of Atlanta; *Secretary*, Dr. Robert B. Osgood of Boston; *Treasurer*, Dr. G. G. Davis of Philadelphia; *Member of Executive Committee*, Dr. John Ridlon.

The next place of meeting will be Washington, D. C., in connection with the Congress of American Physicians.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Illinois State Board of Health.

July 20-22, 1909.

ANATOMY.

1. What becomes of the umbilical vein of the fetus?
2. Where and from what do the colic arteries arise, and what are the distributions?
3. Describe the articulations of the tibia.
4. From where are the renal arteries derived and into what do the renal veins pass?
5. Where does the trigeminus or fifth pair of cranial nerves arise and what are the branches?
6. What bones compose the orbit of the eye?
7. Where and how do the cavities of the greater and lesser omenta connect?
8. In fracture of the neck of the radius, what muscle draws the upper fragment outward and what ligament limits the extent of the displacement?
9. What is the origin, insertion, nerve supply, and action of the semimembranosus muscle?
10. What are the principal venous trunks? What veins are without valves?

PHYSIOLOGY.

1. What effect would rapid heart with aortic regurgitation have on general blood pressure? Give reasons in detail.
2. Name the different pulse waves usually recorded by the sphygmograph.
3. Explain difference between clonic and tonic contraction as applied to muscle fiber.
4. Discuss the relation of the ovaries to menstruation.
5. What are proteids? How are they digested?
6. What are the functions of the saliva? What glands secrete it?
7. What kinds of food would you recommend in cases of obesity?

NEUROLOGY.

1. Name three frequent causes of abscess of the brain.
2. Define and give the symptoms of congenital hydrocephalus.
3. Give etiology, symptoms, and treatment of facial paralysis.

MATERIA MEDICA AND THERAPEUTICS.

1. Outline the general management of fevers, and explain the physiological action of drugs which lower temperature.
2. Name four of the safest antipyretics, giving the dose and therapeutic indications.
3. Give the indications for use of diuretics. Name one of each of the three principal classes, and give the physiologic action of one of them.
4. Give the indications for the use of cardiac stimulants, and name three, with dose and mode of administration of each.
5. Name three of the animal extracts used in medicine, giving doses and indications for use.
6. Give the indications for the use of alteratives. Name three and give doses.
7. What are the indications for the use of expectorants? Name three and give dose of each.
8. Give the physiological action of belladonna.
9. What are the uses of the following: Male fern, ergot, antipyrine, bismuth, sulphate of magnesia, carbonate of magnesia?
10. Give the physiological action of digitalis.

CHEMISTRY.

1. Write the equation representing the action which takes place by treating potassium chlorate with sulphuric acid.
2. Of what does turpentine consist?
3. What is the general formula of the monobasic acids?
4. Complete the following equations: $HgSO_4+2NaCl=$
5. Give the formulæ of the chlorate, bromate, iodate, and sulphate of sodium.

ETIOLOGY AND HYGIENE.

1. What is the etiology of interstitial hepatitis?
2. What is the etiology of acute parenchymatous nephritis? Is only one or are both kidneys affected?
3. What is the etiology of Addison's disease (melasma suprarenale)?
4. What are the main points to be observed in a general disinfection?
5. What is the advantage in adding a small amount of sulphate of aluminum to impure water?

PATHOLOGY.

1. Describe the lesions produced in the liver by syphilis.
2. Mention the conditions of the kidneys which may be brought about by tuberculosis.
3. Describe the modes of formation and appearances of typhoid and of tubercular ulcers of the intestines.
4. In what general respects do "anaemia" and "progressive pernicious anaemia" differ?
5. Describe the formation of an acute abscess.

BACTERIOLOGY.

1. Describe methods of culture and staining of the bacillus of diphtheria.
2. Name the microorganisms most commonly found in connection with acute endocarditis.
3. What bacteria are associated with inflammation and suppuration?
4. What special culture medium is required for the growth of the gonococcus?
5. Describe the specific organism of tetanus, and state its peculiar culture characteristics.

PRACTICE.

1. Give the symptoms and treatment of chronic diarrhea.
2. Give the etiology, symptoms, diagnosis, complications, and treatment of chorea.
3. Give symptoms, dangers, diagnosis, and treatment of bronchial asthma.
4. Give diagnosis, complications, dangers and treatment of chronic contracting nephritis.
5. Give diagnosis of acute endocarditis, differentiating from chronic, and outline fully the management and treatment.
6. Give the diagnosis and treatment of chronic gastritis.
7. Differentiate hemiplegia due to apoplexy from that due to thrombosis or embolism, and give the treatment and prognosis.
8. Give the etiology, symptoms, and treatment of myxedema, and distinguish from cretinism.
9. Give the diagnosis and treatment of pleurisy with effusion.
10. Give treatment of insomnia.

PHYSICAL DIAGNOSIS.

1. Give symptoms and physical signs of pericardial effusion.
2. Give symptoms and physical signs of hydrothorax.
3. Give symptoms and physical signs of pulmonary abscess.
4. Give symptoms and physical signs of aneurysm of the arch of the aorta.
5. Give symptoms and physical signs of cirrhosis of the liver (atrophic form).

OPHTHALMOLOGY AND OTOLOGY.

1. Give etiology, symptoms, and treatment of iritis.
2. Give etiology, symptoms, and treatment of corneal ulcer.
3. Outline your treatment in a case of chronic otitis media (suppurative).

PEDIATRICS.

1. Give etiology, symptoms, and treatment of enterocolitis.
2. Give your treatment in a case of marasmus.

SURGERY.

1. What are the dangers to the patient during and after thyroidectomy?
2. Differentiate appendicitis from distended gall bladder.
3. Define the following terms: Nephrolith, nephrolithotomy, nephrorrhagia, and nephrorraphy.
4. Differentiate hip-joint disease from congenital dislocation of the hip.
5. Outline surgical treatment of varicocele.
6. Describe the varieties of fracture of the scapula, and give the treatment of each.
7. Name the structures which are severed in an amputation at the lower third of the leg.
8. Classify tumors and state in what tissues of the body each is found.
9. Outline proper surgical treatment of aneurysm of the brachial artery.
10. Name the different varieties of wounds, and give treatment of each.

OBSTETRICS.

1. Describe segmentation. Where and at what period does it occur?
2. Describe the changes occurring in the mucous membrane of the uterus during uterogestation.
3. Enumerate and classify the signs of pregnancy.
4. What are the mental disturbances that may occur during pregnancy?
5. Describe hour-glass contraction, and give treatment of same.
6. Describe an embryo at two months.
7. Enumerate the congenital malformations of the head and face of a child, and state at what period of uterogestation the arrested development occurs.
8. In an ordinary accouchement, what precautions should be observed to prevent infection?
9. Under what conditions is obstetric anesthesia to be employed? What anesthetic do you prefer, and how should it be administered?
10. Discuss the indications for forceps delivery and the application and manipulation of forceps.

GYNECOLOGY.

1. Differentiate a fibroid tumor from a pelvic inflammatory deposit.
2. Give methods of treatment of carcinoma of the uterus when a radical operation is not indicated.
3. Give the etiology, symptoms, and treatment of stenosis of the cervix.
4. Give the causes and treatment of pelvic peritonitis.
5. Give the etiology, symptoms, and treatment of anteflexion of the uterus.
6. Give the causes, diagnosis, and treatment of inversion of the uterus.

LARYNGOLOGY AND RHINOLOGY.

1. Name the causes and give the appearances of edema of the larynx.
2. Give the symptoms and results of adenoid vegetations if untreated.

MEDICAL JURISPRUDENCE.

1. Describe rigor mortis, and mention some of the conditions which promote its early appearance.
2. Differentiate a burn inflicted before death from one made after death.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

July 20-22, 1909.

ANATOMY.

1. The umbilical vein of the fetus dwindles and becomes the round ligament of the liver.

2.

	ARISE FROM	DISTRIBUTION
Ileo-colic.....	Superior Mesenteric.	Ileum, cecum, ileo-cecal valve, vermiform appendix.
Right colic....	Superior Mesenteric.	Ascending colon.
Middle colic..	Superior Mesenteric.	Transverse colon.
Left colic....	Inferior Mesenteric.	Descending colon.

3. *The Tibia articulates: Above,* with the femur and fibula; *below,* with the fibula and astragalus.

4. The renal arteries are derived from the abdominal aorta. The renal veins pass into the inferior vena cava.

5. TRIGEMINUS, OR FIFTH PAIR OF CRANIAL NERVES. *Origin:* (1) *Superficial,* from the side of the pons varolii; (2) *Deep* (sensory roots) from the medulla and upper part of cord; (motor root) from floor of fourth ventricle and side of the aqueduct of Sylvius.

Branches: (1) *Ophthalmic,* giving off the: Lacrymal, Frontal, and Nasal. (2) *Superior Maxillary,* giving off the: Meningeal, Orbital, Spheno-palatine, Posterior superior dental, Middle superior dental, Anterior superior dental, Infraorbital, Palpebral, Nasal, and Labial. (3) *Inferior Maxillary,* giving off the Recurrent, Internal pterygoid, Masseteric, Deep temporal, Buccal, External pterygoid, Auriculotemporal, Inferior dental, and Lingual.

6. The bones which enter into the formation of the orbit are: The frontal, sphenoid, ethmoid, superior maxillary, malar, lacrymal, and palate.

7. The greater and lesser peritoneal cavities connect by means of the foramen of Winslow.

8. In fracture of the neck of the radius the upper fragment is drawn outward by the Supinator brevis; the orbicular ligament limits the extent of the displacement.

9. SEMIMEMBRANOSUS. *Origin:* Tuberosity of ischium. *Insertion:* Inner tuberosity of the tibia, posterior ligament of the knee, and popliteal fascia. *Nerve supply:* Great sciatic. *Action:* To flex the leg upon the thigh; then inward rotation; also extension of the thigh.

10. *The veins without valves* are: The venæ cavæ, hepatic veins, portal vein and its branches, renal, uterine, ovarian, pulmonary, cerebral, spinal, and umbilical veins. The sinuses of the skull and very small veins are also without valves.

PHYSIOLOGY.

1. Rapid heart would tend to raise the general blood pressure; in aortic regurgitation the blood pressure would tend to be lowered. Hence in the combined condition suggested in the question the effect on the blood pressure would depend upon the *relative effect* of the two conditions. The one might neutralize the other and the blood pressure be unaltered; or, either might predominate, with corresponding effect on the blood pressure.

2. *The pulse waves usually recorded by the sphygmograph* are: Cataerotic, predicrotic or tidal, dicrotic or recoil, and postdicrotic.

3. In *tonic* muscular contraction the muscle remains for some time in a state of rigid contraction. In *clonic* contraction the muscle alternately contracts and relaxes.

4. *Relation of the ovaries to menstruation:* "It appears to be clearly demonstrated that the phenomenon of menstruation is dependent upon a periodical activity in the ovaries. When the ovaries are completely removed menstruation ceases (artificial menopause), and the uterus undergoes atrophy. When the ovaries are congenitally lacking, or rudimentary, a condition of amenorrhea also exists. These facts and the connection of the ovaries with menstruation are further corroborated in a striking way by experiments upon transplantation or grafting of the ovary. This experiment has been performed upon lower animals (apes) as well as upon human beings. Removal of both ovaries is followed by a cessation of menstruation. Transplantation of an ovary under the skin serves to maintain menstruation, but if subsequently removed this function disappears. An ovary or a piece of an ovary transplanted into the uterus itself or the broad ligament caused a return of the menstrual periods, which had ceased after surgical removal of the glands, or brought on free menstruation in conditions of amenorrhea or dysmenorrhea."—(Howell's *Physiology.*)

5. *Proteid foods* are foods containing proteids. They contain nitrogen, and have a composition similar to that of albumin; other elements contained in them are carbon, hydrogen, oxygen, and sometimes sulphur. Proteids are digested (1) in the stomach, where the pepsin of the gastric juice splits them into proteoses and peptones; and (2) in the small intestine, where they are similarly treated by the trypsin of the pancreatic juice.

6. *The functions of the saliva* are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste; (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar. Saliva is secreted by the parotid, submaxillary, and sublingual glands.

7. *Foods recommended in case of obesity:* Dry foods, with diminished carbohydrates. Ebstein's diet for obesity is as follows: "Breakfast consists of a cup of black tea, without sugar or milk, and two ounces of buttered toast. Dinner, which is given at noon, comprises a meat soup or broth; four to six ounces of boiled or roasted fat beef, with meat gravy, not thickened; one or two fresh vegetables in moderation, and for dessert, salads and fresh or dried fruits. He allows a little light wine and black tea, without milk or sugar. Supper includes tea as before, a soft-cooked egg, and a moderate allowance of fish, ham, or cold fat meat, an ounce of thin, buttered bread or toast, and fresh fruit."

NEUROLOGY.

1. *Three frequent causes of abscess of the brain:* Microbic infection following (1) chronic inflammation of the middle or internal ear; (2) caries of ethmoid, nasal, or orbital bones; (3) compound fracture of the skull, with direct infection from the wound.

2. *Congenital hydrocephalus* is an abnormal accumulation of fluid in the ventricles of the brain. *Symptoms:* The head is of great size and may obstruct delivery; convulsions, drowsiness, separation of the cranial sutures, bulging of the fontanels, thinning of the bones of the head, and fluctuation may all be present. The forehead is prominent;

the child looks wasted, the head is spherical, and the eyes seem prominent.

MATERIA MEDICA AND THERAPEUTICS.

1. The *general management of fevers:* Attack the cause when possible (*e.g.* quinine in malaria); diminish heat production; increase heat loss (diaphoretics); diminish the amount of nitrogenous food; keep the bowels moderately open; keep up the heart's strength with stimulants, when necessary, and treat complications as they arise. A large, well ventilated room, with absence of unnecessary furniture, and absolute cleanliness are also necessary.

The following table (from Potter's *Materia Medica*) gives the chief temperature depressants, with their manner of action: Temperature depression may be done by five different actions working upon two principal lines, viz., by:

(*a*) *Lessening heat production by*
- (1) diminishing tissue change.
- (2) reducing the circulation.

(*b*) *Promoting heat loss by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration, its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above-named actions, to which the numbers refer in each case, viz.:

Quinine, 1.	Aconite, 2.	Antipyrin, 1, 4.
Phenol, 1.	Alcohol, 1, 3.	Antimony, 2, 4.
Salicin, 1.	Nitrous ether, 3, 4.	Cold bath, 5.
Digitalis, 2.	Acetanilid, 1, 4.	Cold drinks, 5.
	Phenacetin, 1, 4.	Wet-pack, 5.

3. *Indications for the use of diuretics:* (1) To remove excess of fluid from the tissues, as in dropsy; (2) to dilute the urine; (3) to promote the elimination of waste products or poisonous material from the blood, and (4) to maintain the action of the kidneys.

(1) *Hydragogue diuretic:* Digitalis. (2) *Stimulant diuretic: Juniper.* (3) *Refrigerant diuretic:* Potassium acetate.

6. *Indications for the use of alteratives:* Conditions of faulty nutrition; perversions of metabolism; chronic disease or poisoning; cachexias and dyscrasias.

Three alternatives: Mercury, dose of calomel, gr. j; arsenic, dose of Fowler's solution, ♏iij; iodine, dose of Potassium iodide, gr. vijss.

8. *Physiological action of belladonna:* Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall; stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

CHEMISTRY.

1. $KClO_3 + H_2SO_4 = KHSO_4 + HClO_3$.

2. Turpentine consists of a stearoptene (such as rosin or colophony) and an eleoptene (such as oil of turpentine).

3. There is no general formula for the monobasic acids. In organic chemistry the monobasic acids all have one COOH (carboxyl) group; the acetic series has the general formula, $CnH_{2n}O_2$.

4. $HgSO_4 + 2NaCl = HgCl_2 + Na_2SO_4$.

5. The formula of Sodium chlorate is $NaClO_3$; of Sodium bromate, is $NaBrO_3$; of Sodium iodate, is $NaIO_3$; of Sodium sulphate, is Na_2SO_4.

ETIOLOGY AND HYGIENE.

1. The *etiology of interstitial hepatitis:* Alcohol, syphilis, obstruction of bile ducts, long continued malaria, stimulating and highly spiced food; infectious fevers, heart disease. It is most common in males of middle age.

2. The *etiology of acute parenchymatous nephritis:* Exposure to cold and wet, acute specific fevers (especially scarlet fever and endocarditis), irritating drugs (turpentine, cantharides, potassium chlorate), extensive burns, and pregnancy. Both kidneys are affected.

3. The *etiology of Addison's disease:* Tubercular lesions in the suprarenal bodies, strains and injuries to the back, blows upon the abdomen, hemorrhage into the suprarenal bodies. More common in men.

5. The addition of the sulphate of aluminum tends to purify the water, if calcium carbonate is also present. Calcium sulphate is thus formed, and this, with aluminium hydrate, entangles floating particles and carries them to the bottom of the vessel.

PATHOLOGY.

1. *Lesions produced in the liver by syphilis:* "In the early stage there are pale grayish nodules, varying in size from a pea to a marble. The larger present yellowish centers at first, but later there is a pale yellowish, cheese-like nodule of irregular outline, surrounded by a fibrous zone, the outer edge of which loses itself in the lobular tissue, the lobules dwindling gradually in its grasp. This fibrous zone is never very broad; the cheesy center varies in consistence from a gristle-like toughness to a pulpy softness; it is sometimes mortar-like from cretaceous change. When numerous, the most extensive deformity of the liver is produced in the gradual healing of these gummata. On the surface there are deep, scar-like depressions, and the entire organ may be divided into a cluster of irregular masses, held together by fibrous tissue."—(Osler's *Practice of Medicine.*)

2. *The condition of the kidneys which may be brought about by tuberculosis:* Tubercles first form in the medullary portion of the kidneys; these coalesce, then caseate and soften. Cavities are thus formed, separated from each other by fibrous tissue. Ultimately the whole substance of the kidney may be destroyed; the pus is discharged in the urine, causing tuberculous pyelitis, and later, perhaps, pyonephrosis.

3. In the *typhoid ulcer* (1) the main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation.

In *tubercular ulcer* (1) the long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined, but rather funnel-shaped and irregular; (4) it is not apt to perforate, but it does not tend to heal, rather to spread.

4. *Anemia* is a general term, including a variety of conditions, and indicating that the blood is reduced either in quantity, in coloring matter, or in number of red cells. These conditions are often more or less associated.

Progressive pernicious anemia is a definite disease, of unknown origin, in which the number of the red cells is greatly diminished, the red cells are also changed in size and shape, nucleated red cells are present, and the disease tends to a fatal termination.

BACTERIOLOGY.

1. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C.

Method of staining: It stains with any aqueous solution of an anilin dye, and quite characteristically with Loeffler's alkaline methylene blue. Neisser's stain is also recognized. The bacilli also stain well by Gram's method.

2. The *microorganisms most commonly found in connection with endocarditis* are: *Streptococcus pyogenes, Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus,* pneumococcus, gonococcus, *Bacillus tuberculosis,* Eberth's bacillus, *Bacillus anthracis, Bacillus coli communis,* and *Micrococcus lanceolatus.*

3. The *bacteria associated with inflammation and suppuration* are: *Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus, Streptococcus pyogenes,* pneumococcus, gonococcus, *Bacillus coli communis, Bacillus pyocyaneus,* typhoid bacillus, *Micrococcus tetragenus.*

4. The special culture medium required for the growth of the gonococcus is blood serum or ascitic or pleuritic fluid.

5. The bacillus of tetanus is characterized by its peculiar spore, formed at one end of the bacillus, and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium, and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

PRACTICE.

7. *"Cerebral Hemorrhage* occurs after the age of fifty-five, as a rule, with atheromatous arteries and an hypertrophied heart. The onset is sudden, with coma, during

exertion or excitement. The temperature falls in an hour, and then rises, sometimes to 106°. Gradual recovery of consciousness takes place in from three to five days, with permanent hemiplegia.

"*Cerebral embolism* comes at any age, with heart disease or after childbirth. There is a sudden onset, without loss of consciousness or with slight mental confusion, or with rapid return to consciousness. The temperature does not fall, but may rise as high as 102°. Improvement occurs within twenty-four hours to a marked degree, but after three or four days the symptoms return. Monoplegia, hemiplegia, or aphasia may remain. Jacksonian epilepsy may develop if the lesion is cortical, involving a special center.

"*Cerebral thrombosis* occurs at any age, but chiefly in syphilitic persons and middle-aged men. There are usually premonitions. The onset is slower, without coma, but with dullness of the mind. The temperature does not fall, but may rise to 100°. The paralysis is similar to that observed in embolism.

"The diagnosis between these three conditions is hardly ever positive."—(Caillé's *Differential Diagnosis.*)

PHYSICAL DIAGNOSIS.

1. *Pericardial effusion:* Area of cardiac dullness is increased, the heart sounds are muffled, other organs may be displaced, dyspnea is present, the apex beat may be displaced to the left, the pulse is feeble, precordial pain and palpitation are present, the precordium bulges.

2. *Hydrothorax:* Bilateral effusion, distended chest, vocal fremitus is absent, there is dullness on percussion, breath sounds and vocal resonance are absent or distant, neighboring organs may be displaced, dyspnea and cyanosis are present, Skodaic resonance is obtained above the effusion.

3. *Pulmonary abscess:* Fever, sweats, chill, leucocytosis, dyspnea, cough, purulent sputum with lung tissue, cavernous breathing, pectoriloquy.

4. *Aneurysm of arch of aorta:* Palpitation, difference in radial pulses (sometimes), dysphagia, dyspnea, cough, change in voice, pressure on nerves may cause irritation or paralysis, edema, intense pain, murmur, there may be a swelling of expansile character and with a thrill, and tracheal tugging.

5. *Atrophic cirrhosis of the liver:* Ascites, hemorrhoids, hematemesis, anorexia, nausea, gastric congestion, vomiting, constipation, muddy skin, first enlargement, later contraction of liver, jaundice is a late symptom, emaciation, pallor, enlarged spleen, distended veins on abdomen, caput medusæ.

PEDIATRICS.

2. *Treatment of marasmus:* The diet must be carefully investigated and regulated. If the child is breast-fed, the milk must be examined as to its composition, and the health and mode of life of the mother inquired into. In bottle-fed babies absolute cleanliness of bottles, nipples, and milk pans must be insisted on. If diarrhea is marked, it may be necessary to stop the use of milk for a time. Whey and barley water or peptonized milk may be used instead. After the diet has been regulated a dose of castor oil or calomel and magnesia may be given to clear away irritating substances. Or Gray powder and Dover's powder may be given. The child should be warmly clad, and should be taken in the open air as much as possible. Colon irrigations may be beneficial.

SURGERY.

1. *The dangers of thyroidectomy* are: Sudden death during the operation, suffocation, dyspnea, cardiac inhibition; tetany or acute myxedema may follow.

2. In *appendicitis:* The pain is at first diffuse, but later becomes localized over the appendix in the right iliac fossa; nausea, vomiting, and constipation may be present; tenderness over the appendix and rigidity of the right rectus abdominis muscle are present; there is generally moderate fever.

In *distended gall-bladder:* The pain is more severe and sudden, and is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; all the symptoms come on more suddenly.

3. *Nephrolith* is calculus of the kidney.

Nephrolithotomy is an operation for the removal of calculus from the kidney.

Nephrorrhagia is hemorrhage from or into the kidney.

Nephrorrhaphy is the suturing of a floating kidney (to the posterior abdominal wall).

7. *The structures severed in an amputation at the lower third of the leg* are: Skin; fascia; muscles, Peroneus longus, Peroneus brevis, tendo Achillis, tendon of Plantaris, Tibialis anticus, Tibialis posticus, Extensor longus hallucis, Extensor communis digitorum, Flexor longus hallucis, Flexor longus digitorum; Arteries, anterior tibial, posterior tibial, peroneal; Veins, anterior tibial, posterior tibial, peroneal, external saphenous, internal saphenous; Nerves, anterior tibial, posterior tibial, musculocutaneous, internal saphenous; Bones, tibia and fistula; and interosseous membrane.

OBSTETRICS.

3. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Subjective signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

4. *The mental disturbances that may occur during pregnancy* are: Changes in temper and disposition, the moral sense may be elevated or lowered, delusions may be present.

10. *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault: A.* Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. *B.* Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(From Jewett's *Practice of Obstetrics.*)

Conditions necessary for the use of forceps are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

LARYNGOLOGY AND RHINOLOGY.

1. EDEMA OF THE LARYNX. *Causes:* Wounds of neck or larynx, burns or scalds of larynx, quinsy, aneurysm, whooping cough, erysipelas, syphilis, tuberculosis, malignant disease, inflammations, diphtheria, Bright's disease, pneumonia.

Appearances: The epiglottis is swollen, and the affected mucous membrane is pale and semi-translucent.

2. *Symptoms of adenoids:* Mouth-breathing; snoring; open mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters.

Effects: Earache and other ear affections; mental deficiency; frequent attacks of coryza; nose-bleed; stunted growth; convulsions, laryngismus stridulus, and various other neuroses may also be noticed.

MEDICAL JURISPRUDENCE.

1. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order. It is said to be due to the coagulation of the muscle plasma.

Conditions which promote the early appearance of rigor mortis: Deaths from exhaustion, or violence, or electricity; when the muscular system is fatigued.

2. In *burns* produced *before death:* There is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous; occasionally there will be no blister if there has been excessive shock; also there will be a red line of demarcation between the injured and the

uninjured parts, and this, being a vital process, is only developed during life.

In *burns* produced *after death* there is no true blister, no red base, and gas only is present in place of the serous fluid.

BULLETIN OF APPROACHING EXAMINATIONS †

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 7
Colorado	S. D. Van Meter, 1725 Tremont Street, Denver	Denver	Oct. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 9
Delaware	J. H. Wilson, Dover	Dover	Dec. 14
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Oct. 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 10
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 12
Idaho*	W. F. Howard, Pocatello	Boise	Oct 5
Illinois	J. A. Egan, Springfield	Chicago	Oct. 20
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 11
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	F. P. Hatfield, Olathe	Kansas City	Oct. 12
Kentucky	J. N. McCormack, Bowling Green	Louisville	Dec. —
Louisiana	F. A. LaRue, 211 Camp Street New Orleans	New Orleans	Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta	Nov. —
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 14
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Nov. 9
Michigan	D. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 12
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Oct. 5
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 12
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	
Montana*	Wm. C. Riddell, Helena	Helena	Oct 5
Nebraska	C. A. Carr, Lincoln	Lincoln	Nov. 10
Nevada	S. L. Lee, Carson City	Carson City	Nov. 1
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	Jan. 4
New Jersey	E. L. B. Godfrey, Camden	Trenton	Oct. 19
New Mexico	J. A. Massie, Santa Fe	Santa Fe	Oct. 11
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Feb. 1
N. Carolina	B. K. Hays, Oxford	Wrightsville	June 15
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	Oct. 5

Virginia	R. S. Martin Stuart	Lynchburg	Dec. 15
Washington*	T. C. McFadden, Seattle	Spokane	Jan. 4
W. Virginia	H. A. Barbee, Point Pleasant	Parkersburg	Nov. 9
Wisconsin	J. M. Beffel, Milwaukee	Milwaukee	Jan. 11
Wyoming	S. B. Miller, Laramie	Laramie	Oct. 20

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

New York now recognizes the license of Delaware, if earned on examination. This makes five States with which New York reciprocates, the others being Michigan, New Jersey, Ohio, and Vermont.

Texas.—At the June examination there were 182 applicants; 152 passed, 23 failed, 6 withdrew, and 1 was expelled.

Alabama.—At the latest examination 155 presented themselves, and of these 73 were successful.

Filipino Students.—The recent graduation of a class of Filipino physicians from the Philippine Medical School marks an epoch in the higher educational work of the American Government in the Philippines. Filipino women are also in hospital training as nurses.

Genital Tuberculosis in Woman.—C. Lenormant says that genital tuberculosis is rare and is almost always secondary to tuberculosis in some other part of the body, often the lungs. It may result as a primary condition from coition with a male who has genital tuberculosis, but this is exceedingly rare. In three per cent. of laparotomies for gynecological troubles there is a tuberculous lesion found. This is usually a descending affection conveyed by the blood-vessels. The vagina is only infected when there are lesions of the mucous membrane. Tuberculosis is rare where there is pavement epithelium. It is more frequent in the fundus uteri, tubes, and ovary. There may be ulcerations or infiltrations of the surface. On the cervix it forms cauliflower growths; in the fundus there is a chronic localized endometritis. When the tubes are involved the peritoneum is also attacked. Surgical interference is generally necessary to bring about a cure.—*Progrès Médical.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of September 18, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	501	132
Diphtheria	206	16
Measles	82	7
Scarlet Fever	48	4
Smallpox	—	—
Varicella	14	—
Typhoid Fever	276	24
Whooping Cough	52	17
Cerebrospinal Meningitis	7	5
Malarial Fever	—	—
Totals	1,186	205

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended September 17, 1909:

THE ADVERSE INFLUENCE OF DIABETES IN CERTAIN OPERATIONS ON THE EYE.*

BY CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

IT is known to all ophthalmologists that, in certain cases of diabetes, disastrous results have followed operations upon the eye. For a number of years the author has been led to study the varying conditions of all diabetic patients in his private practice, before as well as after operating, with a view to determine, if possible, what class of diabetic patients, if any, are not fit subjects for operative interference. I have not succeeded in making any exact discrimination of such patients, and I am still very much in doubt when to operate, if at all, in the presence of undoubted diabetes. It is a recognized fact in general surgery that certain types of diabetics stand operations badly. The wounds do not heal, but become gangrenous along the edges, and no apparent attempt at repair occurs. On the other hand, many patients, whose general condition cannot clinically be distinguished from the others, do unusually well after operations, the wounds healing promptly. How are we to decide what cases can be safely operated with a favorable prognosis as to results?

Diabetic patients are generally anemic, the hemoglobin percentage is reduced, and as a result there is a lowered power of resistance. It has been satisfactorily proved that diabetes interferes with the success of surgical operations, because the sugar circulating in the blood is hygroscopic, and draws water from all the tissues of the body and makes them dry. This arrests or retards the process of repair, by limiting the capacity of the leucocytes to furnish alexins to meet the toxins in the blood, and by preventing the proper development of new repair-cells.

Diabetes is a grave disease. Life often seems to hang by a thread, and this thread is often severed by a very trifling accident. We must consider the general condition of the patient, and learn to properly appreciate how far our treatment is successful in reducing the amount of sugar in the system, and in maintaining the nutrition at a high standard. We must learn to understand the state of the circulation as indicated by the pulse pressure and the cardiac impulse, as this will help us to recognize the presence of possible complications. If we study our cases carefully, we will learn how frequently the diabetic condition is associated with general arteriosclerosis, and with tuberculosis. These three diseases have more than an accidental inter-relationship. In the case of arteriosclerosis, nutritional changes in the pancreas, due to sclerosis of the pancreatic arteries, has been suggested as the cause of diabetes. With regard to tuberculosis, about fifty per cent of the cases of diabetes are tuberculous or there is tuberculosis in the immediate family. Clinical and experimental evidence show that the two diseases, when existing concurrently, do not necessarily influence each other for the worse; but it is possible that similar factors form the predisposing cause for each. It has been noted by more than one keen observer that an increase in the number of cases of diabetes is attended by a decrease in the number of cases of tuberculosis. Arteriosclerosis is frequently found associated with diabetes, and in many of these cases, the glycosuria is the least important feature of the case, and diminishes or disappears when the cardiac angina and other vascular symptoms yield to treatment.

Diabetes mellitus seems to be increasing in frequency, and the belief that an hereditary predisposition underlies most cases is gaining credence. It is a generally accepted statement that the later in life the disease manifests itself, the better the prognosis, but that a permanent cure is seldom if ever effected.

Almost all authors advise postponing any operation on a diabetic patient until repeated urinalyses show that the sugar has disappeared from the urine. But we now know that it is not the amount of sugar, or even its presence, which is of the greatest importance, but rather the amount of acetone, diacetic acid, and beta-oxybutyric acid present, which give us a more accurate idea of the existing condition of the patient. The urinalysis may show little or no sugar in the urine, and yet in these very patients the odor of acetone is very strong in the expired breath; an evidence of the abnormal product of decomposition of the glucose.

As is too well known, operations on the eyes of patients with advanced diabetes have been followed by fatal results, the patients dying in coma. During the coma the urine is usually free from sugar, even if it has been abundant prior to the attack. The coma may set in within twenty-four hours after the operation, or it may be postponed for several days. In some of the cases which were followed by unfortunate complications, the diabetes was accompanied by gastrointestinal symptoms and by enlargement of the liver, but the latter gradually subsided. It is probable that the pancreas was also diseased in these cases, as chronic pancreatitis is of very frequent occurrence in chronic diabetes. A prolonged and close observation of the cases under my care, which were followed by various complications, seemed to offer evidence of a greater deficiency of fermentative action than in other cases free from these complications. Whether psychic, nervous or organic influences were originally at fault in these cases, it was evident that the prognosis for operation

*Read at the meeting of the American Ophthalmological Society, July 14, 1909.

was more unfavorable, the more marked was the defective metabolism of the carbohydrates. Whether this failure of fermentative action in these cases occurs through the blood-current and tissues of the body, or in the digestive tract, we do not yet know. It is not wise to introduce a strict anti-diabetic regimen in a patient immediately before operating, especially if the patient has not been accustomed to it. On the other hand, such a regimen, to which the patient has for a considerable time become accustomed, should not be interrupted at the time of operation. In other words, any change from the general routine of nutrition should not be made in any patient immediately before the operation. The complications which have occurred in my experience after operations on diabetics, have been mainly either iritis, hemorrhages into the anterior chamber, or an infection of the wound as manifested by slow healing. In the cases of iritis there was a marked maceration of the pigment epithelium of the iris, a fact long since pointed out by Snellen. I have also noticed a rather marked tendency to infection by microorganisms after operations on diabetics, and it is known that this has been observed in other branches of surgery. In view of these facts it would seem wise to have tests made of the bactericidal power of the blood-serum in diabetes.

The relatively frequent coexistence of arteriosclerosis and diabetes needs further careful study, for this arteriosclerosis is probably the cause of the recurring intraocular hemorrhages which have been so often observed, especially if the peripheral arteries are involved in the process.

A careful analysis of the one hundred and fifteen cases, on which various operations were performed, has been made, and such conclusions as I have been able to draw are based on the results of such analysis. Of the one hundred and fifteen operations, sixty-two were cataract extractions, forty were preliminary iridectomies, nine were iridectomies for optical purposes owing to the presence of central corneal opacities, and four were iridectomies for chronic glaucoma. Of the sixty-two cataract extractions, forty were senile cataracts in diabetic patients, and all the patients were sixty-five years of age or over. These were all extractions with iridectomy, and all the patients recovered without any serious complications, though the wound healed slowly in eleven cases. There were no hemorrhages and no sign of infection in any of the cases. Many of these patients came under my care before the period of careful observation of the heart and arteries, such as is now made, and before we had the means of carefully estimating the intravascular tension. But of these forty cases I have accurate records of the condition of the heart, arteries, and intravascular tension in ten cases. These ten cases showed slow healing of the wound, and all gave evidence of arterial degeneration and a high intravascular tension. The remaining twenty-two cases were all pure diabetic cataracts; that is, they were cortical cataracts, bluish-white in color, and somewhat swollen. The patients' ages varied from thirty-six to forty years. In each case, before operation, care was taken to reduce the percentage of sugar to a minimum, and as far as possible to eliminate the abnormal products, acetone, diacetic acid and oxybutyric acid. In six of the twenty-two cases there was a somewhat profuse hemorrhage into the anterior chamber, which recurred several times. In two cases there were retinal hemorrhages, which did not recur and were slowly absorbed. In six cases the operation was followed by iritis, without much exudation, which was obstinate in resisting treatment, and a discission of the opaque capsule was necessitated in two cases. In the remaining eight cases there were no complications either at the time of the operation or following it, and the wounds healed promptly with excellent results as to vision. In fourteen of the twenty-two cases there were signs of arteriosclerosis in the conjunctival vessels, and after the extraction of the cataracts the same condition was found in the retinal arteries. In the remaining eight cases no signs of arterial degeneration were demonstrable. In the second list of operations, forty cases of preliminary iridectomy in cataract patients, twenty-two were senile cataracts in diabetic patients, whose ages varied between sixty and sixty-eight years, and eighteen were true diabetic cataracts in patients under forty years of age. In the twenty-two cases of senile cataracts no case of iritis occurred after the iridectomy, but in three cases there was an annoying hemorrhage into the anterior chamber and the external wound healed very slowly, and in these three cases the signs of general arteriosclerosis were present. In the eighteen cases of true diabetic cataract iritis occurred in four cases, but owing to prompt treatment no permanent synechiæ were formed. Two of these four cases were victims of pulmonary tuberculosis, but showed no evidence of arterial degeneration.

In the third list of operations there were nine iridectomies for optical purposes, owing to central corneal opacities. There were no anterior or posterior synechiæ and no signs of intraocular irritation. They were all young diabetics, under forty years of age, and with one exception all did well, the wounds healing promptly. The one exception was a lady, aged twenty-two, in whom the operation was followed by severe iritis with an abundant exudation, which blocked the pupil for a long period, and it was not until five months later that the pupil became free and useful vision restored to the eye. In all of the nine patients the fellow eye was normal.

In the fourth and last class of operations there were four iridectomies for chronic glaucoma performed before the field of vision was much contracted, and as soon as the diagnosis was positively made. In these cases great care was taken to choose the time for the operation when the percentage of sugar was either nil or very small, and when the urinalysis showed only a minute percentage of acetone and diacetic acid. All four cases did badly, and one patient fell into collapse and nearly died. Three were men and one was a woman. Profuse hemorrhage into the anterior chamber occurred in all four cases and recurred several times, but there were no retinal hemorrhages. In the fourth case, a lady aged fifty-nine, there was a profuse hemorrhage into the anterior chamber which recurred on the two succeeding days. At the close of the third day the patient complained of great pain and in a few hours became delirious. There was a distinct odor of acetone in her breath and I looked for the speedy onset of diabetic coma and death. Fortunately, after twenty hours of delirium, the mental excitement passed away without developing into coma and the patient temporarily recovered. The glaucomatous symptoms seemed to be arrested, the tension returned to the normal and the vision was improved. Eight months later, however, the patient succumbed to an attack of diabetic coma.

An analysis of Uhthoff's paper on Cataract Extraction in Diabetics, presented at the meeting of

the Ophthalmological Society in Heidelberg, in 1908, yields the following results: There were one hundred and fifteen cataract operations and 68 per cent. recovered vision of 1 to 1/3. Iritis occurred in 6 per cent. and glaucoma in 1 per cent. There were hemorrhages into the anterior chamber in 8.9 per cent. Hemorrhages into the retina in 4.5 per cent. Hemorrhages into the vitreous in 1.8 per cent. Retinitis occurred in 2.6 per cent. No eye was lost, but two patients had only light perception. One patient died on the fifth day after the operation in diabetic coma.

In all the statistics published on the subject, iritis seems to have been the most frequent complication. This is probably because the tissues in diabetes are more prone to inflammatory processes in consequence of diminished powers of resistance and the greater virulence of microorganisms in diabetic patients.

I believe that the retinal and vitreous hemorrhages are far more serious in their prognosis as to results than is usually appreciated. So far as it is possible to draw any conclusions from my own experience, I am induced to offer the following:

1. We must carefully differentiate those diseases which are directly due to diabetes as a cause from those which may occur independently of the disease.
2. The abnormal products of metabolism, acetone, diacetic acid and oxybutyric acid seriously complicate the prognosis, and must, as far as possible, be eliminated before any operation is undertaken.
3. Arteriosclerosis plays an important rôle in the etiology of the disease and its complications.
4. The prognosis does not depend on the percentage of glucose in the urine, but on the degree of acid intoxication.
5. The possible connection between diabetes and tuberculosis needs more searching investigation before any positive opinion can be formulated.

JOINT TUBERCULOSIS; WITH SPECIAL REFERENCE TO ITS PATHOLOGY.*

PRELIMINARY STUDY OF FORTY-FIVE CASES

By LEONARD W. ELY, M.D.,

NEW YORK.

SURGEON TO THE SEA BREEZE HOSPITAL, CONSULTING ORTHOPEDIC TO ROOSEVELT HOSPITAL, ETC.

THIS paper is based upon an examination of a number of tuberculous joints in the laboratory, and upon a study of the histories of the patients from whom the specimens were taken. It is an attempt to bring together, so to speak, the study of surgery and pathology, and has been done under the auspices of the Department of Surgery at the College of Physicians and Surgeons, New York, and especially under the guidance of Dr. William C. Clarke.

The specimens assembled are forty-eight in number, from forty-five patients. Of these, forty-five are joints, one a specimen of bone alone, and two of tendon sheaths. There are sixteen knees, six hips, two shoulders, nine elbows, seven ankles and feet, four wrists and hands. Of these, thirty-four were tuberculous, and eleven showed no sign of tuberculosis. The specimen of bone alone was from tuberculous disease of the humerus which did not involve the joint. Of the tendon sheaths, both were sent in with a diagnosis of tuberculosis. One was tuberculous and the other was not.

*Read at the annual meeting of the American Orthopedic Association, Hartford, Conn., June 14, 1909.

The first fact that strikes one in a classification of the material is the large number of apparently incorrect diagnoses. The operators by whose courtesy the laboratory came into possession of the specimens are about twelve in number, some of them of great ability. Under these circumstances it seems remarkable that of the ten joints in which no tuberculosis was found nine should have been sent to the laboratory with a diagnosis of tuberculosis. On the other hand, four joints were sent in as nontuberculous, in which tuberculosis could be demonstrated by the microscope. It may be argued of the former class that tuberculosis may have been present in the specimen and may not have been discovered in the laboratory, or may have died out. This is, of course, possible, but the number of such cases must be very small, for any tuberculous process capable of giving symptoms justifying a resection or amputation would almost invariably produce changes in the joint so marked that they could be recognized by a careful pathological examination.

FIG. 1.—Tuberculosis of the elbow; synovial type, showing the tuberculous process making its way through the periosteum into the bone under the margin of the articular cartilage. Section through the coronoid process; × about 20 diameters. The articular cartilage is seen to the left; the synovial membrane above.

Here we have two practical hints. First, that no pains should be spared in arriving at a correct diagnosis before proceeding to a radical operation on a supposed tuberculous joint; and, second, that we should accept with great reserve any statistics of tuberculous joints cured by conservative means, when these statistics are based upon the unsupported clinical opinion of the man who has compiled them. If it is possible to err so frequently when the clinical diagnosis is apparently confirmed by the gross examination of the resected joint, how much more liable to error is the clinical diagnosis alone!

The next thing that strikes one's attention in a

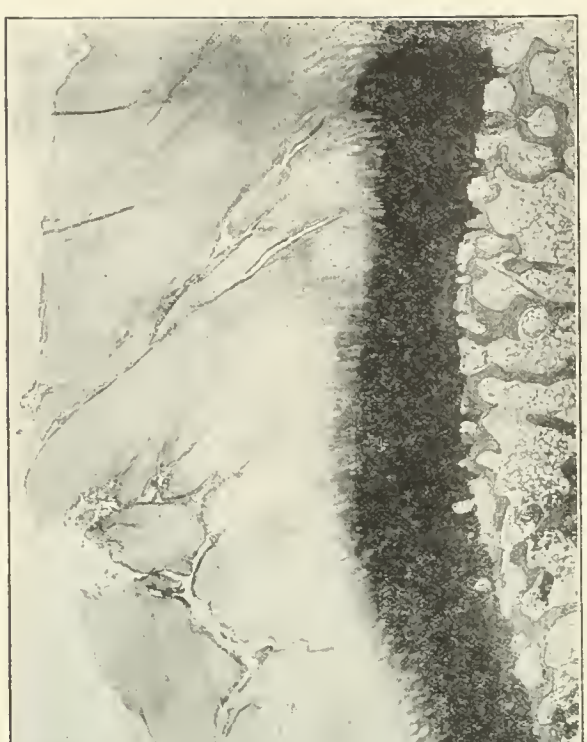

Fig. 2.—Synovial tuberculosis; section from the patella, showing fibrillation and fraying of the articular cartilage; × 20 diameters.

study of these cases is the rather large proportion which are apparently primarily synovial.
